To those who believed in glial cells
during the long, dark period
when the neuron concept dominated brain science.

This page intentionally left blank

Preface

Non-neuronal cells, termed neuroglia, were recognized as independent elements of the nervous system nearly a century and a half ago by Virchow. These cells are present in primitive nervous systems and, undoubtedly driven by positive evolutionary pressures, have persisted in high density and acquired greater diversity in mammals. Knowledge about glial cells has accumulated at a phenomenal rate in the last 30 years, and has become relevant to all fields of neurobiology. With so much new information at hand, we felt that this was an important time to assemble the facts about these cells as we presently understand them.

Historically, glial cells were viewed as a type of CNS connective tissue whose main function was to provide support to the true functional cells of the brain, the neurons. This firmly entrenched concept remained virtually unquestioned for the better part of a century. But glial cells are neither connective tissue nor mere supportive cells. In contrast to early beliefs, glial cells are now recognized as intimate partners with neurons in virtually every function of the brain, and as participants in the pathophysiology of the dysfunctional or diseased brain. These cells have been challenging to study, however, because their functions are not associated with easily recorded electrical signals as is the case with neurons.

While books about the nervous system have grown in size and complexity attempting to accommodate the frantic production of new neuroscience information, the incorporation of new facts about glia has not kept pace. One simply can not learn about glial cells by turning to the typical neuroscience textbook (*From Neuron to Brain* by Nicholls, Martin and Wallace, is a notable exception). This curious fact has also been a motivation for bringing together in the present volume a detailed summary of what is currently known about these cells. It will, we hope, also encourage better integration of the glial and neuronal information bases, which each suffer in the absence of the other. The brain can not be understood as the functional sum of two isolated cellular compartments; it must, we think, be seen as a single entity containing neurons and glial cells working in seamless harmony with one another. Somehow, this essential message has gone too long undelivered.

Glial research is at a particularly exciting point in its evolution. Great advances in our knowledge about nervous system diseases have opened the door for thinking about the role of glial cells in the pathogenesis of these conditions and in their treatment. Therapies that would literally have been the stuff of science fiction only a decade ago are now in advanced stages of testing. Patients with Parkinson's disease who no longer respond to our best medicines, for example, have received brain tissue transplants, whose effectiveness may be enhanced by including glial cells as factories for the production of trophic substances. Glial transplants to refurbish areas of demyelination may also be possible in the near future. Our capacity to measure the brain's functional molecules and determine their cellular topography has revealed a baffling array of neurotransmitters, receptors, ion channels, adhesion molecules, and trophic factors associated with glial cells. These findings are stimulating and broadening the field of glial research. They provide critical insights about how neurons and glial cells might communicate with each other, and reveal an astonishing overlap between the features of the brain's two principle cell types that would have been heresy not long ago.

The many experts who wrote chapters for this volume contributed in other val-

uable ways as well. Before the writing began, they provided invaluable advice about what topics should be covered. In an unselfish manner, they adjusted the scope of their individual contributions so that they fit the context of the book as a whole. To enhance the quality and utility of the chapters, each underwent a stage of peer review and this was cheerfully provided by other authors. The editorial burden was significantly lightened by the satisfaction of dealing with this uniquely talented and energetically committed group of authors. They shared our view of the importance of developing a compendium volume about glial cells, and continuously reinforced our enthusiasm for the project as it moved forward. We acknowledge their essential partnership in the making of Neuroglia, and thank them for their efforts.

One point should be made in concluding. As impressive as our gains in glial cell knowledge have been, the best is yet to come. Glial researchers have struggled with our own version of the Heisenberg uncertainty principle: How to study the role of glial cells in the multicellular actions of the nervous system without interfering with the very functions we wish to understand? Our initial efforts were a compromise. We retreated somewhat from the immense complexity of the intact nervous system in favor of simplified preparations that allowed more rigorous study. This reductionistic approach has produced a mountain of provocative information, as detailed here, but few definitive answers. Consequently, we have long lists of glial cell properties while the list of proven functions is small. But starting with these demonstrated properties, testable hypotheses of glial cell function can now be formulated with greatly improved precision, taking full advantage of new or refined research technologies. A rich yield of vital new insights about the functions of neuroglia should follow and future editions of this book will survey those benefits.

Contents

I MORPHOLOGY

1. Morphology of astrocytes 3
   Alain Privat, Minerva Gimenez-Ribotta, and Jean-Luc Ridet
2. The morphology and ultrastructure of oligodendrocytes and their functional implications 23
   Sara Szuchet
3. Basic biology of the Schwann cell 44
   Richard P. Bunge and Cristina Fernandez-Valle
4. Ependymoglia and ependymoglia-like cells 58
   Andreas Reichenbach and Stephen R. Robinson
5. Microglial cells 85
   Wolfgang J. Streit
6. Morphology of nonmammalian glial cells: functional implications 97
   N. Joan Abbott

II LINEAGE

7. Methods of studying glial cell lineage 119
   Jack Price
8. The origins and lineages of macroglial cells 135
   Robert P. Skoff and Pamela E. Knapp
9. *In vitro* studies of the development, maintenance and regeneration of the oligodendrocyte-type-2 astrocyte (O-2A) lineage in the adult central nervous system 149
   Guus Wolswijk and Mark Noble
10. Development of microglia 162
    Sergey Fedoroff

III PHYSIOLOGY

11. Potassium channels 185
    Steven Duffy, Douglas D. Fraser, and Brian A. MacVicar

12. Voltage-gated sodium and calcium channels 202
Harald Sontheimer and J. Murdoch Ritchie

13. Distribution and transport of chloride and bicarbonate ions across membranes 221
Wolfgang Walz

14. pH regulation 230
Joachim W. Deitmer

15. Transport of neuroactive amino acids in astrocytes 246
Arne Schousboe and Niels Westergaard

16. Na,K-ATPase and its isoforms 259
Kathleen J. Sweadner

17. Modulation and control of intracellular calcium 273
Steven M. Finkbeiner

18. Modulation of glial potassium, sodium, and chloride activities by the extracellular milieu 289
Klaus Ballanyi

19. Gap junctions 299
Bruce R. Ransom

20. Electrophysiology of mammalian glial cells *in situ* 319
George G. Somjen

IV RECEPTORS

21. Gamma-aminobutyric acid and glutamate receptors 335
Gabriela v. Blankenfeld, Kristian Enkvist, and Helmut Kettenmann

22. Acetylcholine and serotonin receptor activation 346
Wolfgang Walz

23. Astroglial adrenergic receptors: expression and function 354
Ken D. McCarthy, Kristian Enkvist, and Yanping Shao

24. Peptide receptors on astrocytes 367
Graham P. Wilkin, Derek R. Marriott, and Brian Pearce

25. Eicosanoid, purine, and hormone receptors 377
Brian Pearce and Graham P. Wilkin

V MECHANISMS OF CELL-TO-CELL COMMUNICATION

26. Extracellular space as the pathway for neuron-glial cell interaction **387**
Charles Nicholson

27. Functional significance of glial-derived matrix during development and regeneration **398**
Robert J. McKeon and Jerry Silver

28. Tenascin and janusin: glial recognition molecules involved in neural development and regeneration **411**
Andreas Faissner and Melitta Schachner

29. Growth factors and their receptors in the peripheral nervous system **427**
Michael Sendtner

30. Growth factors and their receptors in the central nervous system **441**
G. Labourdette and M. Sensenbrenner

31. Effects of nerve impulses on glial membranes **460**
Richard K. Orkand

VI MOLECULAR AND BIOCHEMICAL MECHANISMS

32. Energy metabolism **473**
Bernd Hamprecht and Ralf Dringen

33. Glia-specific enzyme systems **488**
Heinrich Wiesinger

34. Second-messenger systems **500**
Martha L. Simmons and Sean Murphy

35. Early-response gene expression in glial cells **510**
Alaric Arenander and Jean de Vellis

36. Lipid metabolism **523**
Julian N. Kanfer

VII MYELIN

37. Biochemistry of myelin proteins and enzymes **535**
Sammye Newman, Megumi Saito, and Robert K. Yu

38. Molecular biology of myelination 555
Anthony T. Campagnoni

39. Neurological mouse mutants: a molecular-genetic analysis of myelin proteins 571
Klaus-Armin Nave

40. Axoglial interactions at the cellular and molecular levels in central nervous system myelinated fibers 587
Stephen G. Waxman and Joel A. Black

VIII MEMBRANE STRUCTURE AND CYTOSKELETAL PROTEINS

41. Glial membranes and axoglial junctions 613
Jack Rosenbluth

42. Cytoskeletal organization of myelinating Schwann cells 634
Grahame J. Kidd and Bruce D. Trapp

43. Intermediate filaments in astrocytes 650
Lawrence F. Eng and Yuen Ling Lee

IX GLIA AS PART OF THE IMMUNE SYSTEM

44. Microglia and neuronal dysfunction 671
Dana Giulian

45. Antigen presentation by central nervous system glia 685
Hartmut Wekerle

46. Cytokine production 700
Etty N. Benveniste

X NEURON-GLIAL CELL INTERACTIONS

47. Glial cell regulation of extracellular potassium 717
Eric A. Newman

48. The role of glia in the inactivation of neurotransmitters 732
David L. Martin

49. Radial glial cells: scaffolding for brain construction 746
Pasko Rakic

50. Formation of the blood-brain barrier 763
Hartwig Wolburg and Werner Risau

51. Schwann cell functions in saltatory conduction 777
S. Y. Chiu

52. Glial cells and the supply of substrates of energy metabolism to neurons 793
Jonathan A. Coles

53. Glial cells and activity-dependent central nervous system plasticity 805
Christian M. Müller

54. Release of neuroactive amino acids from glia 815
Giulio Levi and Vittorio Gallo

XI ROLE OF GLIA IN INJURY AND REGENERATION

55. Glial cells and regeneration in the peripheral nervous system 829
S. A. Gilmore and T. J. Sims

56. Gliosis 843
Amico Bignami and Doris Dahl

57. Oligodendrocyte inhibition of nerve fiber growth and regeneration in the mammalian central nervous system 859
Martin E. Schwab

58. Transplantation of glial cells 869
W. F. Blakemore, A. J. Crang, and R. J. M. Franklin

59. Microglia in experimental neuropathology 883
Jochen Gehrmann and Georg W. Kreutzberg

60. Glial cells and axonal regeneration in the central nervous system 905
Claudia A. O. Stuermer

XII GLIA AND DISEASE

61. Brain edema 919
Harold K. Kimelberg

62. Epilepsy 936
Uwe Heinemann, Claudia Eder, and Antje Laß

63. Hepatic encephalopathy **950**
Michael D. Norenberg

64. Glial response to brain ischemia **964**
Richard P. Kraig, Christopher D. Lascola, and Anthony Caggiano

65. Idiopathic and 1-methyl-1-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-Induced Parkinsonism **977**
Donato A. Di Monte and J. William Langston

66. Inherited disorders of myelination of the central nervous system **990**
Ian D. Duncan

67. Viral infections of neuroglial cells **1010**
Monique Dubois-Dalcq

68. Alzheimer's disease **1027**
Richard B. Banati and Konrad Beyreuther

69. Gliomas **1044**
Paul Kleihues, Hiroko Ohgaki, and Adriano Aguzzi

Index **1065**

Morphology

This page intentionally left blank

1 Morphology of astrocytes

ALAIN PRIVAT, MINERVA GIMENEZ-RIBOTTA, AND JEAN-LUC RIDET

It is generally acknowledged that Virchow (1846) discovered the existence of another element, besides neurons, in the central nervous system. However, the first account of neuroglia was probably that of Dutrochet (1824), who described small globules (*corpuscules globuleux*), he observed in great quantities on the surface of large globules (*cellules globuleuses*), in the nervous system of mollusks. But Virchow used the term *Nervenkitt*, which was later translated as *neuroglia*, to account for "a connective substance formed in the brain and the spinal cord in which the nervous system elements are embedded." Even though our present concepts have been modified to a large extent, Virchow's original description of a tissue that is able to fill all spaces between nerve elements still holds true. The major contribution of Deiters (1865), was to view those cells that do not have an axon as nonneuronal cells. Two of his original pictures, reproduced by Somjen (1988), could correspond either to small neurons or to oligodendroglia. However, credit for the modern study of glial cells should probably be given to Golgi (1885), whose technique permitted for the first time a reliable *morphological* identification of all cell types in the nervous system of vertebrates.

The distinction between fibrous and protoplasmic astrocytes, often attributed to Ramón y Cajal (1909), was in fact made by Andriezen (1893), who distinguished fibrous glia, found essentially in the white matter, from protoplasmic glia found in the gray matter. This distinction between gray and white matter glia was later substantiated by Kölliker (1893), Azoulay (1894), and Retzius (1894). Ramón y Cajal, first using Weigert stain (1895), then his own gold chloride sublimate method (Ramón y Cajal, 1913) adopted this classification, and he attached the name of "astrocyte" to both cell types. The Weigert stain was especially useful at that time as it permitted Ramón y Cajal to substantiate the difference between fibrous and protoplasmic astrocytes: gliofibrils appeared to be absent in the protoplasmic astrocyte. Later, the gold chloride sublimate method enabled him to recognize that fibrils were present in astrocytes of both gray and white matter.

The extensive use of Golgi's technique enabled Ramón y Cajal to describe a "third element," different from neurons and astrocytes, which was later found by Rio Hortega (1919, 1920), using the capricious silver carbonate methods, to be composed of two different cell types: microglia and oligodendrocytes. All these metallic impregnation techniques led Rio Hortega (1921, 1922, 1933), and Ramón y Cajal (1920), to describe a wide variety of shapes and sizes including a type of "intermediate astrocyte," which had been found in the cerebellum by Terrazas (1897). At the same time, Penfield (1924, 1932) attempted to correlate the morphological characteristics of glial cells, as revealed by metallic impregnations, with the nuclear and cytoplasmic characteristics of those same cells observed on paraffin sections stained with classical histological dyes.

Regarding the possible function of astrocytes, Golgi (1885), noticed the frequent contact of glial processes with blood vessels on the one hand, and with nerve cells on the other, and attributed to them the function of supplying nutrients to the cell body and the axon of nerve cells. His (1889) made the suggestion that embryonic glial cells guide the migration of developing neurons.

In a remarkable essay, Lugaro (1907) adopted the suggestion of His, and made the proposal that adult astrocytes keep the interstitial milieu compatible for the function of neurons. He added that these cells could serve to "chemically split or take up" substances released by nerve cells to ensure communication and excite one another, thus "buffering" their communication in time and space. Ramón y Cajal (1909), rejected Golgi's nutritive theory, and, although he admitted his own ignorance, due essentially to the lack of proper tools to study glial cells directly, he hypothesized that glial cells and their processes serve to insulate nerve fibers, and eventually they proliferate to fill the gaps left by dying neurons in pathological conditions.

In the second half of the twentieth century, the advent of electron microscopy enabled several investigators (Luse, 1956; Farquhar and Hartmann, 1957; Bunge et al., 1960; De Robertis and Gershen-

feld, 1961; Palay et al., 1962), to analyze the ultrastructure of astrocytes, and to describe, among other organelles, the ultrastructural appearance of gliofibrils in fibrous astrocytes. Herndon (1964), and Mugnaini and Walberg (1964), observed that protoplasmic astrocytes also contained gliofilaments. Mori and Leblond (1969) adapted the gold chloride sublimate technique of Ramón y Cajal to electron microscopy, and they found that the metallic deposit was concentrated over gliofilaments.

The biochemical nature of gliofilaments was disclosed by Eng et al. (1971), and Bignami et al. (1972), through the identification of glial fibrillary acidic protein (GFAP). It was then shown by Eng and Kosek (1974), Schachner et al. (1977), and Eng and Bigbee (1978), to be associated to the 8 to 10 nm intermediate filaments of astrocytes, together with vimentin (Dahl et al., 1981; Schnitzer et al., 1981). Nevertheless, numerous astrocytes in the normal brain are negative for GFAP immunocytochemistry (Ling and Leblond, 1973), and GFAP-negative astrocytes predominate in the gray matter (Bignami and Dahl, 1976; Ludwin et al., 1976; Kitamura et al., 1987).

Other specific cell markers detected by immunocytochemistry include the S-100 protein, identified by Moore (1965), which is preferentially expressed in astrocytes (Matus and Mughal, 1975; Ludwin et al., 1976; Cocchia, 1981; Ghandour et al., 1981), the C1 antigen, which characterizes mainly Bergmann glia (Golgi epithelial cells), and retinal Müller cells in adult mammals (Sommer et al., 1981), and the M1 antigen (Lagenaur et al., 1980), which is specific for protoplasmic and fibrous astrocytes.

A special mention should be made of the A2B5 and Ran-2 antibodies, extensively used by Raff and colleagues (Bartlett et al., 1981; Raff et al., 1983a, 1983b, 1984a, 1984b; Miller and Raff, 1984). The monoclonal antibody A2B5, which recognizes many gangliosides in nerve tissue (Fredman et al., 1984), was used initially *in vitro* to differentiate two classes of astrocytes (Raff et al., 1983a). Type 1, present in cultures developed from prenatal optic nerve, is devoid of A2B5 immunoreactivity; type 2, found in cultures derived from postnatal optic nerve, shares the positivity for A2B5 with oligodendrocytes and a common progenitor. This led Miller and Raff (1984) to claim that A2B5 could distinguish inbetween fibrous and protoplasmic astrocytes. However, type 2 astrocytes have never been found *in situ* in the nervous system of vertebrates (Privat and Rataboul, 1986; Skoff and Knapp, 1991). The latter authors, through a very careful combined autoradiographic and immunocytochemical study, have demonstrated that the wave of prenatal generation of astrocytes, claimed by Miller et al. (1985) and based on *in vitro* results, did not exist *in vivo*. Recent studies by Noble (1991) and Espinosa de los Monteros and Zhang (1993), confirmed the view of Mori and Leblond (1969), Privat and Leblond (1972), Paterson et al. (1973), and Privat and Fulcrand (1977), that astrocytes and oligodendrocytes arise from separate precursors, which are the progeny of a common ancestor, located in the ventricular layer before birth and in the subependymal layer postnatally (Smart, 1961; Privat and Leblond, 1972; Privat, 1975; Levison and Goldman, 1993).

Thus, this controversy underlies the enormous gap that exists between *in vivo* studies, which combine ultrastructural examination of cell characteristics with detection of specific epitopes and analyze the actual characteristics and fate of given cell type, and *in vitro* studies, which are best able to explore what cells can do when transported in an artificial environment (Privat et al., 1979). In addition, it is noteworthy that once astrocytes are plated in a culture dish, they can be considered initially as reactive (Bignami and Dahl, 1989). Whatever their morphology (i.e., fibrous or protoplasmic), cultured astrocytes are strongly GFAP-immunoreactive (Figure 1-1).

The goal of this chapter is to describe the morphological characteristics of astrocytes *in vivo*, stressing their diversity of shapes and sizes, and comparing classical metallic impregnations, electron microscopy, and immunocytochemistry.

We have chosen to organize our description around one region of the central nervous system—the spinal cord—where one can demonstrate, in the limited surface of a cross section, radial glia, fibrous and protoplasmic astrocytes, and even subclasses of the latter. However, the different types of astrocytes will also be illustrated in various regions of the brain, such as cerebral cortex, cerebellum, corpus callosum, whenever necessary for the purpose of our description.

MORPHOLOGY OF ASTROCYTES

Light Microscopy

Examination of sections impregnated with the technique of Golgi, modified by Rio Hortega (1918), permits the distinction of three main types of astrocytes according to their spatial organization:, (1) *radial cells*, which are disposed in a plane perpendicular to the axis of the ventricles, and span the whole thickness of the white matter (Figure 1-2A), (2) *fibrous, nonradial astrocytes*, located also in the white matter, which send their processes in various direc-

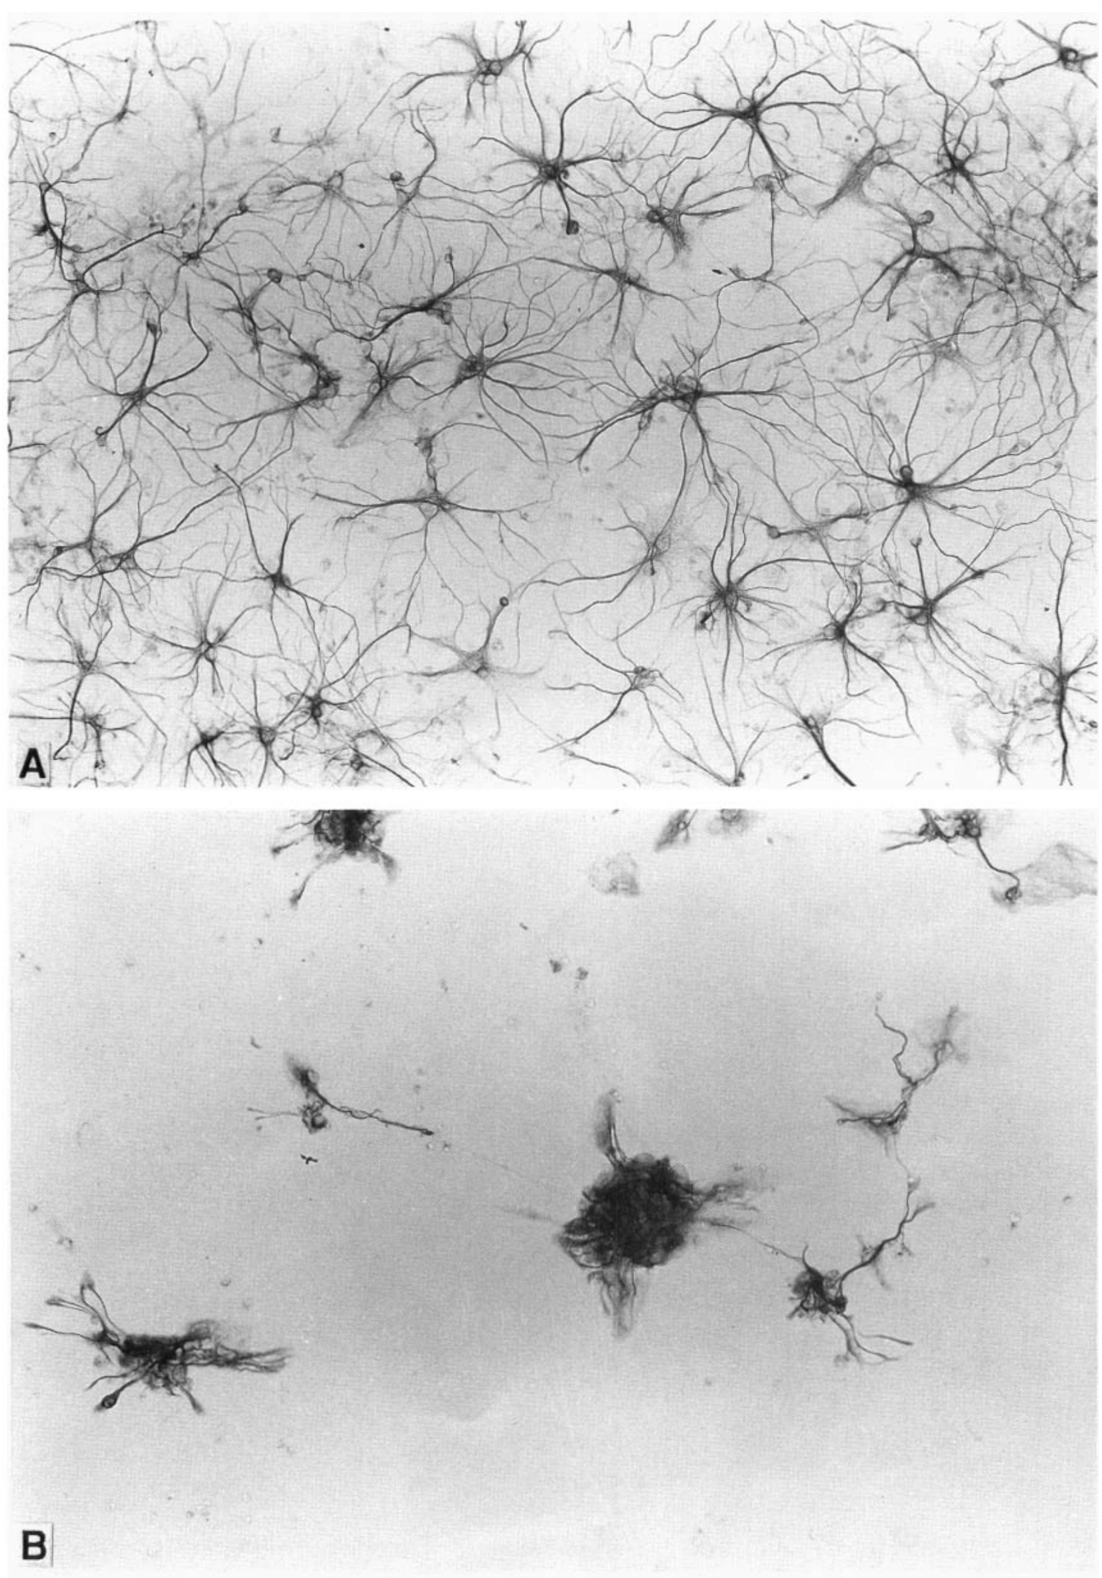

FIG. 1-1. (A) Primary culture of astrocytes from cerebral cortex of day 18 rat fetuses, light microscopy, GFAP immunodetection. Numerous fibrous astrocytes are intensely immunostained. ×250. (B) Primary culture of astrocytes from cerebral cortex of day 18 rat fetuses, light microscopy, GFAP immunodetection. Immunoreactive protoplasmic astrocytes. ×250.

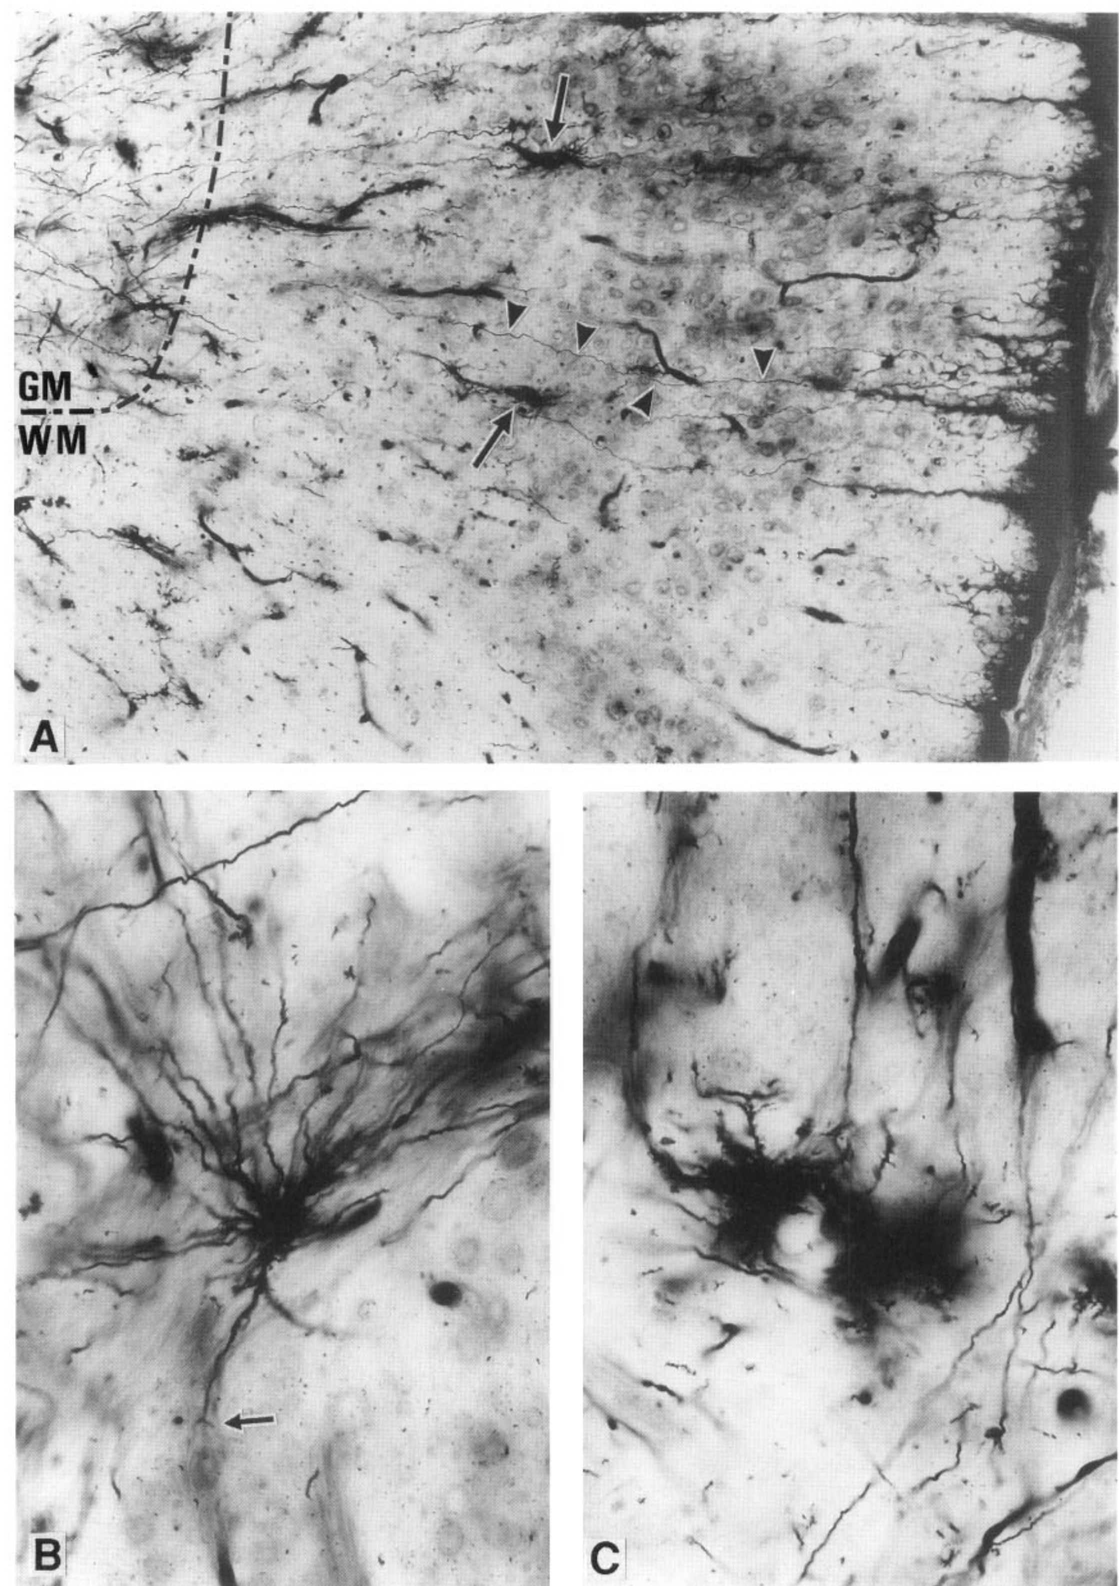

FIG. 1-2. (A) Cat spinal cord white matter, light microscopy, Golgi-Rio Hortega impregnation. Thin long unbranched radial processes (*arrowheads*) can be seen coursing throughout the whole white matter from the pia mater to the gray matter. Two radial astrocytes are clearly observed (*arrows*). *GM*, gray matter; *WM*, white matter. ×125. (B) Cat spinal cord white matter, light microscopy. Golgi-Rio Hortega impregnation. Stellate fibrous astrocyte with long unbranched processes. *Arrow* points to a vascular endfoot. ×375. (C) Cat spinal cord gray matter/white matter border, light microscopy, Golgi-Rio Hortega impregnation. Two protoplasmic astrocytes, characterized by a spherical perikaryon and numerous short and spiny processes, extend a few long fibrous processes (at the top of the figure), in the white matter. ×375.

tions and are not in contact with the pia mater (Figures 1-2B and 1-4B), and (3) *protoplasmic astrocytes*, located in the gray matter, which are characterized by short, ramified crimped processes (Figures 1-2C, 1-3B, and 1-4A). Although transitional forms between the first two types are not rare, we have found only rare evidence of intermediate forms between protoplasmic astrocytes and fibrous ones, which are usually located at the interface of the gray and white matter.

Radial Astrocytes. As described by Ramón y Cajal (1909), with the standard Golgi technique and the method of Weigert, radial astrocytes impregnated with the technique of Golgi-Rio Hortega span the entire white matter, with one process or a group of processes abutting onto the pia matter, and other processes deeply buried in the gray matter. The perikaryon of these cells is located either in close vicinity of the pia matter or at some distance from it. The processes are unbranched, rectilinear, often running in bundles into the fibrous axes of the white matter (Figure 1-2A).

After immunodetection of GFAP (Figure 1-5A), radial astrocytes are readily detected as fibrous axes coursing through the white matter of the lateral and ventral fasciculi. Upon close examination, they do not appear as smooth and unbranched as with the Golgi-Rio Hortega impregnation. Rather, they appear prickly, and somehow irregular in caliber. The perikaryon is usually only partially stained, possibly corresponding to the perinuclear organization of gliofibrils.

After immunodetection of S-100 protein (Figure 1-6A), which is a cytosolic soluble calcium-binding protein (Baudier et al., 1982, Donato, 1986), the perikarya of radial astrocytes and the proximal part of their processes is intensely impregnated. The surface of the cells and processes appears also prickly, as with GFAP. At variance with the latter, if thin processes are stained, they can rarely be followed in continuity with longer processes.

On semithin sections stained with toluidine blue (Figure 1-7), bundles of myelinated axons appear separated by radial, lightly stained axes, along which one can identify light, elongated, sometimes crenated nuclei, whose nuclear envelope is outlined by a thin rim of chromatin. Immunodetection of GFAP evidences a distinct reaction around those nuclei, extending in to the radial axes. These cytological characteristics are in accordance with those described by Ling and coworkers (1973), in the rat corpus callosum, by Sasaki and coworkers (1989), in the cat spinal cord, and are currently used for the identification of white matter astrocytes in semithin sections (Skoff and Knapp, 1991). With this technique, the boundaries of the cytoplasm are not precisely detected; the radial axes in which these astrocyte nuclei are embedded are lightly stained with toluidine blue, contrasting with neighboring oligodendrocytes whose cytoplasm appears denser (Figure 1-7A).

Radial glial cells are present in other locations in the central nervous system of vertebrates. Three cell types have been described in adult animals.

Müller Cells of the Retina. Müller cells are elongated throughout the whole thickness of the retina, from the inner to the outer limiting membrane. Their outer segments are generally stout, extensively anchored together to form the external limiting membrane. Their nucleus is located in the nuclear layer, and many processes radiate from their main axis in plexiform and nuclear layers. Finally, thin processes are inserted between the fibers of the nerve fiber layer, where they intermingle with those of a few astrocytes. In semithin sections, their nucleus appears elongated, sometimes notched with a homogeneous nucleoplasm, and a thin rim of chromatin along the nuclear envelope.

Golgi Epithelial Cells of the Cerebellum (Bergmann Glia). Golgi epithelial cells extend radially through the molecular layer of the cerebellar cortex. Their perikarya are located between those of Purkinje neurons, and they send an apical tuft of rectilinear processes, which end in contact with the pia mater. With metallic impregnations, these processes appear decorated with thin, irregular appendages (Figure 1-8A). At the surface of the cerebellar folia, the endfeet of Golgi epithelial cells constitute a continuous layer of glia limitans. On semithin sections stained with toluidine blue, the nuclei of Golgi epithelial cells appear spherical or ovoid, sometimes elongated along the axis of the folium, and are closely packed between those of Purkinje neurons.

Tanycytes. Tanycytes are radial glial cells whose nucleus is located in the ependymal lining of the ventricles or immediately beneath it. They are present all along the third ventricle, the aqueduct, the fourth ventricle, and the central canal of the spinal cord (for review see Rafols, 1986). With metallic impregnations, their basal process appears to terminated with an endfoot on the pia mater (Figure 1-3A). This is a unique, unbranched process of large caliber whose surface is irregular and which emits short expansions contacting nearby blood vessels (see Chapter 4 for details).

Fibrous Astrocytes. Fibrous astrocytes scattered in the white matter of the spinal cord are less numerous than radial ones. They appear with the metallic impregnation of Golgi-Rio Hortega as stellate cells

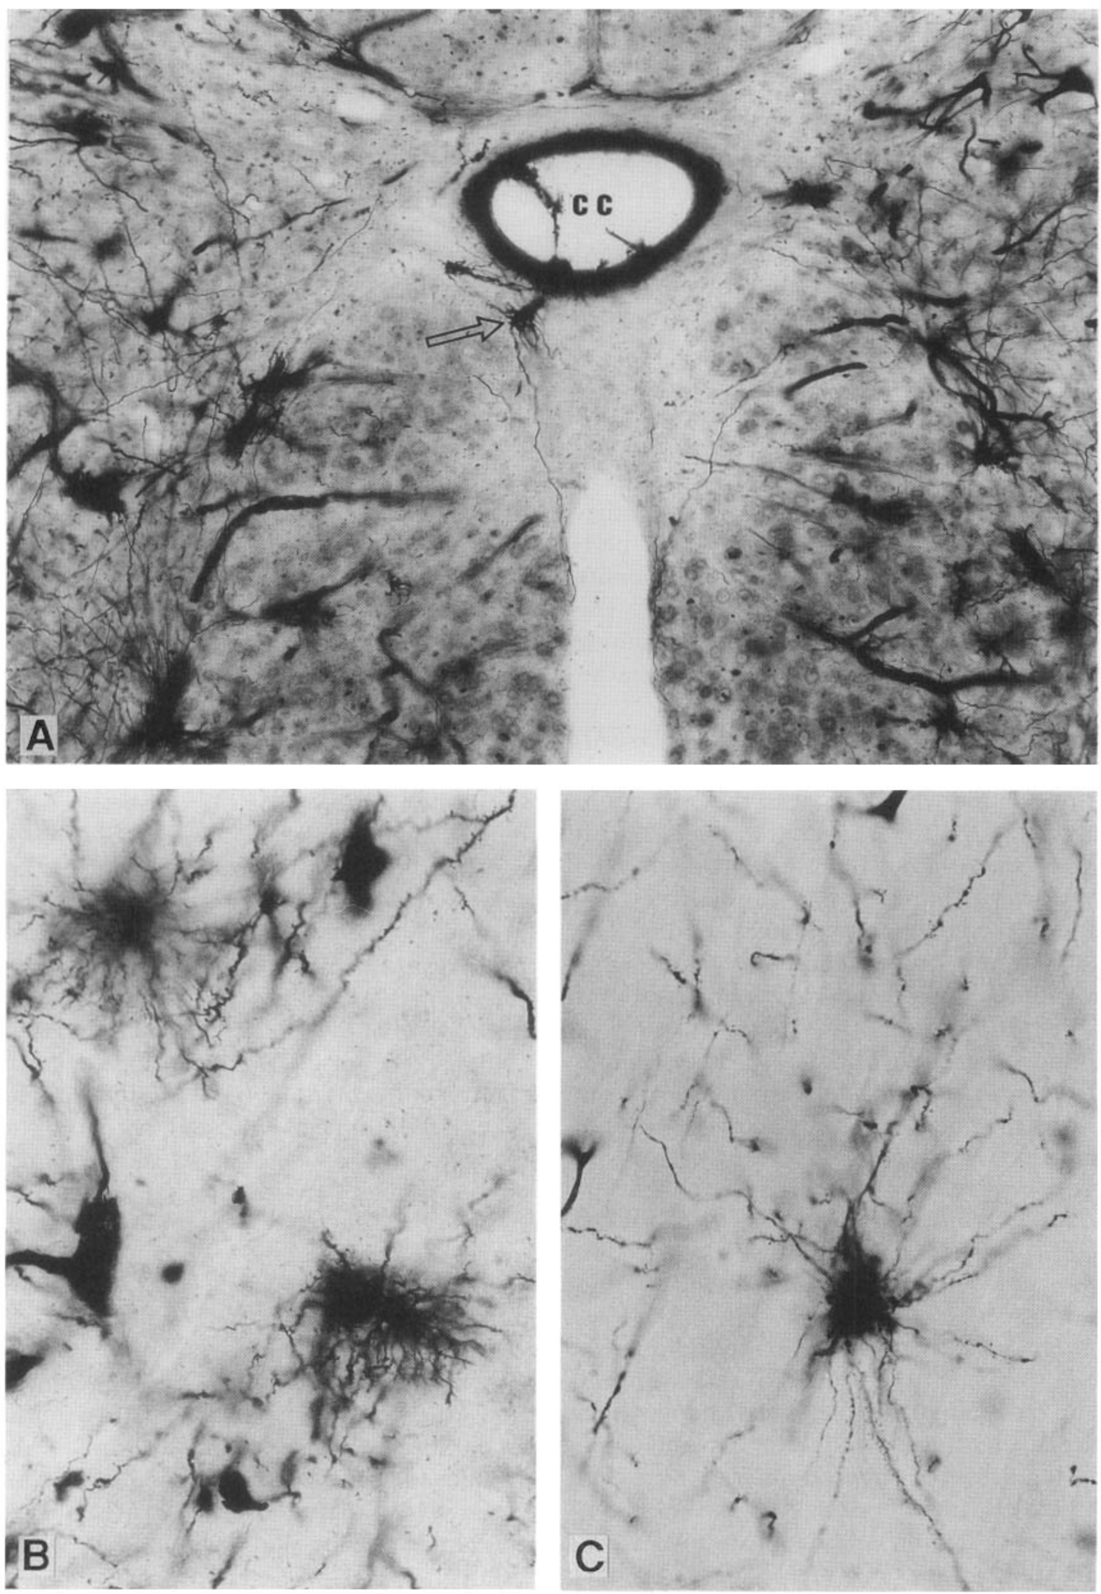

FIG. 1-3. **(A)** Cat spinal cord, light microscopy, Golgi-Rio Hortega impregnation. FIG. 1-8 (**A**) Rat cerebellar cortex, light microscopy, Golgi-Rio Hortega impregnation. Bergmann glial cells (Golgi epithelial cells), exhibit long thin spinous processes abutting onto the pia mater. ×250. (**B**) Rat cerebellar cortex, light microscopy, Golgi-Rio Hortega impregnation. Velate astrocyte with sheet-like appendages (*arrowheads*). ×500.

with long, thin poorly ramified processes (Figure 1-2B). These processes are generally smooth surfaced, and extend over long distances, usually without reaching the pia mater. They sometimes get in contact with blood vessels on which they abut through an expanded endfoot.

After immunocytochemical detection of GFAP, fibrous astrocytes of the white matter appear as stellate cells, whose perikaryon is incompletely stained, and whose processes appear knotted and irregular in shape and caliber (Figure 1-5A).

After immunodetection of S-100 protein (Figure 1-6A), the perikarya are better impregnated than with GFAP. Conversely, the processes appear more fragmented, with a great number of very thin profiles that one can hardly trace back to the parent perikaryon.

On semithin sections, fibrous astrocytes of the white matter can be differentiated from radial ones on the regular spherical or slightly oval shape of their nuclei, which is in the center of a light staining space that radiates in branching fashion in all directions (Figure 1-7B).

Fibrous astrocytes of the spinal cord white matter are in all respects similar to those described by Sasaki and colleagues (1989), and by other authors in other regions of the CNS: corpus callosum (Mori and Leblond, 1969), optic nerve (Peters and Vaughn, 1967). In the cerebral cortex, and specifically the subcortical white matter, impregnation with the gold chloride sublimate method of Ramón y Cajal discloses cells whose morphology is in many respects similar to that evidenced by GFAP immunocytochemistry in the spinal cord (compare Figures 1-4B and 5A).

Protoplasmic Astrocytes. When impregnated by the Golgi-Rio Hortega method, the astrocytes of the gray matter of the spinal cord appear as bushy cells with numerous short processes radiating in all directions. These processes are highly ramified and of variable caliber, contrasting with those of the fibrous astrocytes of the white matter. Some cells whose perikarya are located across the white/gray mattter border may exhibit a composite morphology, with those processes extending in the gray matter exhibiting a protoplasmic morphology, while those that extend through the white matter are of the fibrous type (Figure 1-2C). This strongly suggests that the actual morphology of astrocytes is indeed the reflection of the organization of the tissue in which they are located than of any other intrinsic characteristics (Ramón y Cajal, 1909).

After detection of GFAP, the astrocytes of the spinal cord gray matter appear as small cells with many short processes radiating from a perikaryon which is most often incompletely delineated by GFAP immunoreactive structures (Figure 1-5B,C). The nucleus is always unstained. The processes have a rather smooth outline, and are rarely branched.

After detection of S-100 protein, the perikaryon of astrocytes, including the nucleus, is delicately stained, together with the proximal part of the processes, which appear numerous, of irregular caliber, with an irregular outline and a few branchings. Processes of small caliber are also delicately stained in some regions of the gray matter, such as the superficial part of the dorsal horn (Figure 1-6B). In such instances, those processes do not appear to be in continuity with impregnated perikarya.

On semithin sections stained with toluidine blue, the nuclei of astrocytes appear as regularly spherical or ovoid, with a smooth outline and a regular condensation of chromatin along the nuclear envelope (Figure 1-9A,B). The perinuclear cytoplasm appears light on the background of the neuropile. The processes are not clearly visible at variance with the astrocytes of the white matter, whose processes are more clearly delineated by neighboring myelinated axons and densely stained oligondendrocytes (Figure 1-7A).

In other areas of the central nervous system gray matter, such as cerebral cortex, hippocampus, striatum, cerebellum, the morphology of astrocytes appears basically the same, whether it is evidenced by *in toto* impregnation with metallic deposits (Figure 1-3B,C), or by detection of a specific epitope or finally on a semithin section. There may be slight variations, for instance, in the abundance of GFAP, which is usually greater in hippocampus than elsewhere, or in the shape and size of nuclei, or in the extension and branching of processes (Figure 1-3C). What is evident is that astrocytes adapt their shape and size to the architecture of the tissue, in order to constitute a tridimensional net whose mesh size is adapted to the various functions subserved by the neurons of different regions and their companion glial cells. Specifically, astrocytes of the granular layer of the cerebellum are characterized by sheetlike appendages (velate astrocytes), which extend between the perikarya of granule neurons (Figure 1-8B). Whether their tridimensional architecture is the result of repellant forces (Distler et al., 1991), or interaction with neurons is still a matter of debate.

Ultrastructure of Astrocytes

Ultrastructural examination of all types of astrocytes in the spinal cord and in other regions of the central

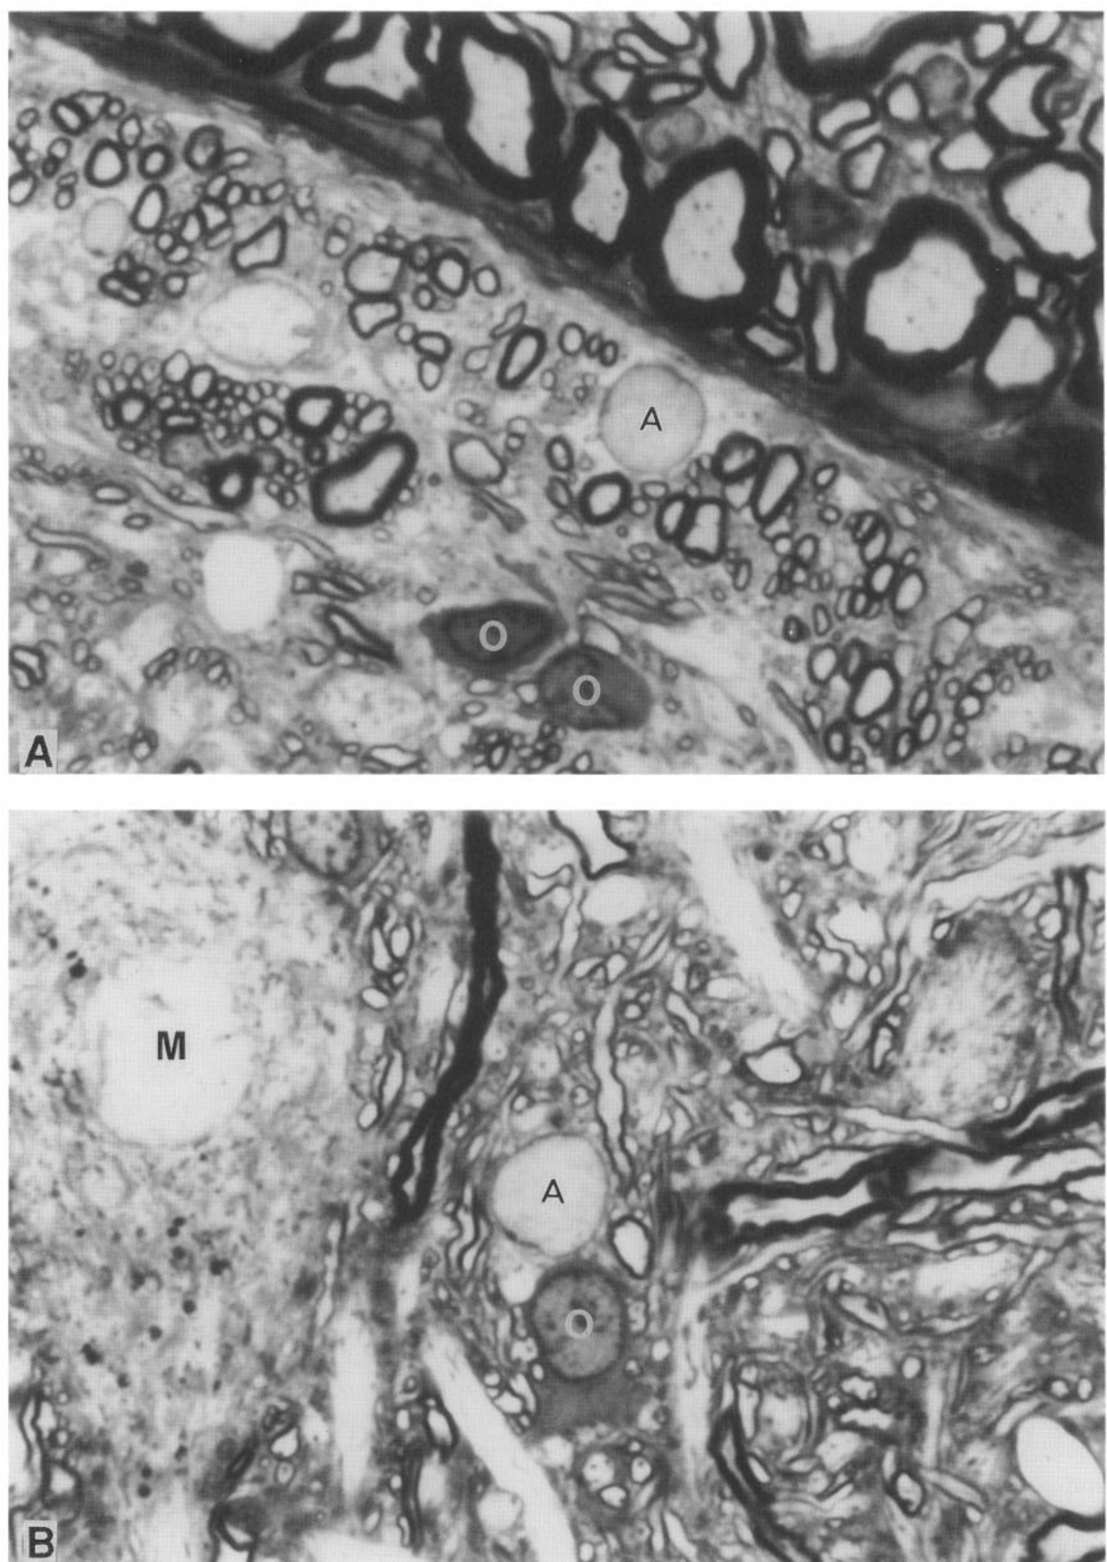

FIG. 1-9. (**A**) Rat spinal cord gray matter, light microscopy, 1 μm section toluidine blue stain. Detail of the dorsal horn showing the perikaryon of a subpial protoplasmic astrocyte (*A*) *O*, oligodendrocyte. ×2500. (**B**) Rat spinal cord gray matter, light microscopy, toluidine blue stain. Semithin section showing a protoplasmic astrocyte (*A*), and an oligodendrocyte (*O*), in the ventral horn. Note the contrast between the staining of astrocyte and oligodendrocyte cytoplasms and chromatins: the former is characterized by a clear cytoplasm and a thin perinuclear rim of chromatin, the latter by a denser and darker cytoplasm and a mottled heterochromatin. *M*, motoneuron. ×2500.

nervous system demonstrates that they share a number of characteristics, and that the rare differences encountered are quantitative rather than qualitative.

As already seen on semithin sections, the nucleus is usually regular in shape, in rare instances with small indentations. With aldehyde fixations, the nucleoplasm appears finely granular (Figure 1-10A), with a distinct condensation of chromatin along the nuclear envelope, which exhibit numerous pores (Figure 1-10A), (Mori and Leblond, 1969; Peters et al., 1976). The ground cytoplasm of the perikaryon is less dense than that of neighboring neurons and oligodendrocytes, and is poor in free ribosomes. The cisternae of rough endoplasmic reticulum are usually short with well-delineated membranes on a light background, and a content that appears denser than the ground cytoplasm. The Golgi region is not extensive, but well delineated in a juxtanuclear position. Mitochondria appear frequently less dense than those of neurons. The most specific organelle is the intermediate gliofilament, 8 to 10 nm in diameter, organized in bundles, whose quantity varies widely from one astrocyte to the other. As a rule, they are much more abundant in fibrous astrocytes of the white matter (Figure 1-11B), and much more abundant in the processes than in the perinuclear cytoplasm. They are specifically decorated with a peroxidase deposit when reacted with anti-GFAP antibody (Figure 1-11A, D). The cytoplasmic contour of astrocytes is extremely irregular; their processes insinuate between neuronal and other glial profiles, and, for instance, most often completely insulate neuronal perikarya from microglial satellites.

Processes emanating from the perikaryon are of variable caliber, usually larger in fibrous astrocytes and even larger in radial astrocytes such as those of the spinal cord white matter or Golgi epithelial cells of the cerebellum (Figure 1-10B). They contain, besides gliofilaments, isolated microtubules, that appear more concentrated in their initial segment, close to the perikaryon (Figure 1-10C). Membrane specializations of astrocytes are of two types: gap junctions involve most often two astrocytes (Figures 1-10D and 1-12A), and more rarely an astrocyte and an oligodendrocyte, or the outer leaflet of a myelinated fiber (Mugnaini, 1982). They are of variable surface and are found on perikarya as well as on processes, with a particular concentration on subpial and perivascular endfeet (Figure 1-12B). The molecular substrate of these astrocyte-astrocyte gap junctions is a protein, connexin 43, which is part of a gene family comprising a dozen protein that have a similar gene structure, and about 50 percent sequence identity at the amino acid level (for review see Dermietzel and Spray, 1993). It has been shown recently that the abundance of gap junctions between astrocytes, that is the expression of connexin 43, displays topographic differences (Dermietzel et al., 1989; Yamamoto et al., 1990). For instance, connexin 43 is more abundant in the hypothalamus than in the striatum (Batter et al., 1992). At variance, gap junctions between oligodendrocytes involve another connexin, connexin 32. Thus, astrocyte-oligodendrocyte gap junctions would eventually be heterotypic junctions, with properties different from those of either astrocytes or oligodendrocytes (for review see Dermietzel and Spray, 1993).

The other characteristic feature of astrocyte membranes, as seen with freeze-fracture, is the so-called orthogonal assembly, described first by Dermietzel (1974), on astrocytes and later found by Privat (1977), on ependymocytes. These assemblies, found only on astrocytes and related cell types (Mugnaini, 1982), consist of paracrystallin arrays of 7-nm subunits, appearing as particles on the P-face and small pits on the E-face. They are especially abundant on astrocyte surfaces apposed onto mesenchymal tissues, that is, the subpial and perivascular endfeet (Figure 1-12B). Whatever the region of the central nervous system, ultrastructural examination reveals that astrocyte processes fill all the spaces between neurons and other glial cells, thus substantiating their role in insulating them from each other. This insulating capacity may take various forms, according to the specific characteristics of neural circuits. We have studied in detail the glial and neuronal environment of a specialized portion of monoaminergic fibers present in the dorsal horn of the cord. It has been demonstrated over the last decade (Maxwell et al., 1983, 1985; Marlier et al., 1991; Rajaofetra et al., 1992; Ridet et al., 1992, 1993), that most of the monoaminergic axonal boutons in the spinal cord dorsal horn did not contribute classical synapses. Reconstruction from serial sections evidenced the absence of postsynaptic densities facing a majority of these axonal boutons (Ridet et al., 1993). Analysis of tissular environment of these varicosities has shown that the proportion of astroglial profiles was higher around serotonergic and noradrenergic varicosities devoid of synaptic specializations. Moreover, the length of the contact between nonsynaptic varicosities and astrocytes was twice as long as that between synaptic varicosities and astrocytes (Ridet et al., 1993). The specialized type of communication corresponding to this morphological organization, the so-called "volume transmission" (Fuxe and Agnati, 1991), could thus involve specialized astrocytes. It is highly likely that careful tridimensional reconstruction, associated with the de-

tection of specific receptors or uptake systems, would reveal exquisite differentiations of astrocytes in almost any region of the central nervous system.

CONCLUSIONS

The study of the morphology of astrocytes tells us two things:

1. There is a great diversity of shapes and sizes of astrocytes and their processes throughout the nervous system. Interestingly, the spinal cord provides a unique example of a region of the central nervous system where all astrocytes subtypes are represented: radial glial, fibrous, and protoplasmic astrocytes. This variety is in accordance with the organization of the different tissue compartments of the cord: the radial arrangement accommodates the funicular organization of descending and ascending axons of the white matter. The few fibrous astrocytes, found mainly in the ventral funiculi, are likely to accommodate the projection of motoneuron axons. Protoplasmic astrocytes of the gray matter are molded upon the complex tridimensional neuropile and, as such, occupy roughly a spherical volume.
2. All these cells have in common the expression of a specific phenotype, including the synthesis of proteins such as GFAP and S-100, the presence of gliofilaments, the qualitative identity of nuclear and cytoplasmic ultrastructural characteristics, and of membrane specializations.

It is not yet totally clear whether the phenotypic diversity results exclusively from the interaction of a common genotype with the tissular environment, or whether a mosaic of phenotypes exist in the neural tube. It is most likely that the two coexist, that is, some degree of diversity is already expressed in early progenitors, a diversity that is later expanded during prenatal and postnatal ontogeny.

Personal results have been obtained with the financial support of IRME, AFM, and D. Heumann Fundation. The authors acknowledge Françoise Sandillon for histological assistance and Jean-René Teilhac for artwork.

2 The morphology and ultrastructure of oligodendrocytes and their functional implications

SARA SZUCHET

Such minute corpuscles could not evoke any aesthetical emotions. Yet these cells, refractory to every protoplasmic staining, because of their infinite numbers, their dissemination in encephalic terrains and their strategic location next to neurons and nerve fibers, deserved, at some point, to seize the attention of neurologists and to be placed on an equal rank with the classic neuroglia. This moment has arrived!

P. d. Rio Hortega (1928)

Oligodendrocytes (OLGs) are defined as the cells that make and maintain central nervous system myelin. This definition came into being only about three decades ago, despite the fact that in 1928 Rio Hortega had clearly shown the association of OLGs with myelin and had postulated the functional similarity of OLGs to Schwann cells (Rio Hortega, 1925). The reason for this protracted uncertainty as to the function of OLGs rests on the inherent refractiveness of OLGs to stains, on the complex nature of OLG-axon interaction and on the intricate topography of the central nervous system.

Without denying recognition to Robertson (1899) and Ramón y Cajal (1913), who visualized cells that, in all probability, were OLGs, I believe that few would argue that it is Rio Hortega (1921, 1922, 1928) who deserves recognition as the discoverer of OLGs. By using innovative metal impregnation techniques based on silver carbonate (Rio Hortega, 1921, 1922) or silver nitrate—a modification of Golgi's technique (Gurr, 1962)—Rio Hortega (1928) rendered the first detailed description of the morphology of cells that he named oligodendroglia (ὀλίγοσ = few; δὲνδρον = tree; γλία = glue). An afterthought prompted Rio Hortega (1928) to change the name to *oligodendrocytes*—in recognition that they were bona fide cells. The importance of Rio Hortega's contribution goes beyond the structural characterization of OLGs; exhibiting great insight, he suggested that OLGs make the myelin sheath and thus are the Schwann cells of the central nervous system.

This chapter deals with the morphology and ultrastructure of OLGs. There are a number of textbooks (e.g., Haymaker and Adams, 1982; Peters et al., 1991) and reviews (e.g., Mugnaini and Walberg, 1964; R. Bunge, 1968; Szuchet and Stefansson, 1980; Szuchet and Dumas, 1983; Wood and Bunge, 1984) that describe these topics comprehensively. One may ask: Is there a need for more of the same? For the sake of completeness, some overlap with the above-cited references is unavoidable, but this chapter is not intended to be a historical, all-inclusive review of findings; rather, the emphasis will be on integrating current concepts and technologies in an attempt to establish a link—however tenuous—between the structure and function of OLGs. Two examples may illustrate some of the perplexities that need to be addressed. On the one hand, OLGs exhibit structural polymorphism, and heterogeneous interaction with axons: Does this imply functional heterogeneity among the myelin-making OLGs? On the other hand, morphology does not appear to be a distinguishing feature between a "perivascular" and a perineuronal OLG: Can it be assumed that they have similar functions? These are some of the issues that are discussed here; unfortunately, much of it is in the realm of speculation.

The development of techniques for isolating and maintaining OLGs in long-term culture (McCarthy and de Vellis, 1980; Szuchet et al., 1980a, 1980b; Gebicke-Härter et al., 1981; Lisak et al., 1981; Hertz et al., 1985) has spurred a strong interest in the biology of OLGs. Witness to this is the large bibliography that has accumulated. While new insights pertaining to the topics discussed here have yet to emerge, advances in the knowledge of signaling events that initiate and control myelin formation and of the mechanisms of gene expression are bound to pave the way for a functional understanding of OLG polymorphism. Paraphrasing Stensaas and Stensaas (1968b), it is axiomatic that the morphology of the various OLG subtypes is related to their respective function.

This chapter is divided into four main sections. The first section reviews current findings on the morphology and ultrastructure of OLGs and discusses them in the context of the classical work of Rio Hortega. The second section examines the functional significance of OLG polymorphism. The third section deals with *in vitro* models and their contribution to our understanding of the OLG structure-function relationship. In the fourth section, the role of the substratum, other central nervous system cell types, and trophic factors in influencing or determining the morphology of OLGs is assessed.

FROM RIO HORTEGA TO THE PRESENT: WHAT IS NEW?

Morphology

The complexity of OLG morphology must have astonished Rio Hortega, for he stated: "If OLGs would represent a type of cell with a uniform morphology as is the case for protoplasmatic or fibrous astrocytes, then a description of their morphology would be a simple matter. As is, OLGs are so polymorphic that each variant has to be characterized independently" (Rio Hortega, 1928). I have chosen to describe the morphology of OLGs as portrayed by three different techniques because each reveals distinct aspects.

Metal Impregnation. Due to a peculiar resistance to stains, OLGs were the last central nervous system cells to be discovered and characterized. Rio Hortega's success where others had failed was in large measure due to his use of silver impregnation techniques, particularly the silver nitrate method (Rio Hortega, 1928). He observed that the ease of impregnation varied among species and explored those that gave the best results (e.g., kittens or dogs); he also observed that delineation of cellular extensions was better in young animals than in old ones. Rio Hortega found OLGs to be distributed throughout the central nervous system, but in higher abundance in the white matter. He noted three kinds of dispositions: (1) alignment of closely apposed cells in rows along nerve fascicles, (2) juxtaposing neuronal somata, and (3) abutting blood vessels (see below). Accordingly, Rio Hortega classified OLGs into interfascicular, perineuronal, and perivascular. Additionally, using criteria such as size of somata, number and characteristics of cellular processes, tissue distribution, and the manner of interaction with axons, Rio Hortega (1928) grouped OLGs into four subtypes, which he numbered I through IV, recognizing nevertheless the absence of transition limits among them.

Type I OLGs (Figure 2-1A) have spherical or slightly polygonal somata (15 to 20 μm) from which abundant, tenuous processes emerge directed toward nerve fibers; they can be found in the forebrain, cerebellum, and spinal cord and are organized around blood vessels, neurons, and fiber tracts. Type II OLGs (Figure 2-1B) are observed only in white matter; they have a polygonal or cuboid shape (20 to 40 μm), have fewer and thicker processes than do type I OLGs, and have a close association with nerve fibers. Type III OLGs, with three to four processes emanating from the somata and directed toward nerve fibers (Figure 2-1C), are localized in the cerebral and cerebellar peduncles, the medulla oblongata and the spinal cord. Finally, type IV OLGs (Figure 2-1D) occur near the entrance of nerve roots into the central nervous system and in association to large axons (Friedrich et al., 1980). They adhere directly to the nerve fibers not unlike Schwann cells (Polak, 1965).

Figure 2-1 illustrates prototypes of each class. It is clear from these photomicrographs that Rio Hortega has captured the full gamut of OLG polymorphism. It is also apparent that no sharp boundaries exist between the various subtypes. For example, the type I cell C in Figure 2-1A bears a closer resemblance to the type II cell (Figure 2-1C) than to type I cell A in Figure 2-1A. This fact has already been emphasized by Rio Hortega (1928). Nonetheless, when one compares cell A in Figure 2-1A with cell A in Figure 2-1D, the difference is impressive. The implications of this polymorphism have yet to be fully realized. One might conjecture that this structural diversity has its functional correlates, but data to support such a contention have been slow in coming. Future research should clarify this issue.

The work of Rio Hortega, confirmed at the time by Penfield (1932) and others, met with a great deal of skepticism, especially in the early days of electron microscopy. But his assertions on the role of OLGs have withstood the test of time, even though his accomplishments are scarcely appreciated even today.

Metal impregnation techniques, although capable of providing detailed information on cell morphology when used by gifted hands, often produce erratic results and therefore have not been fully explored. Nevertheless, Stensaas and Stensaas (1968a) applied the method of Golgi-Rio Hortega to examine OLGs in toad spinal cord and detected a spectrum of OLG morphologies that bore a resemblance to the subtypes in the mammalian central nervous system. Figure 2-2 depicts the range of morphologies seen between two of the prototypes, type I (Figure 2-2A)

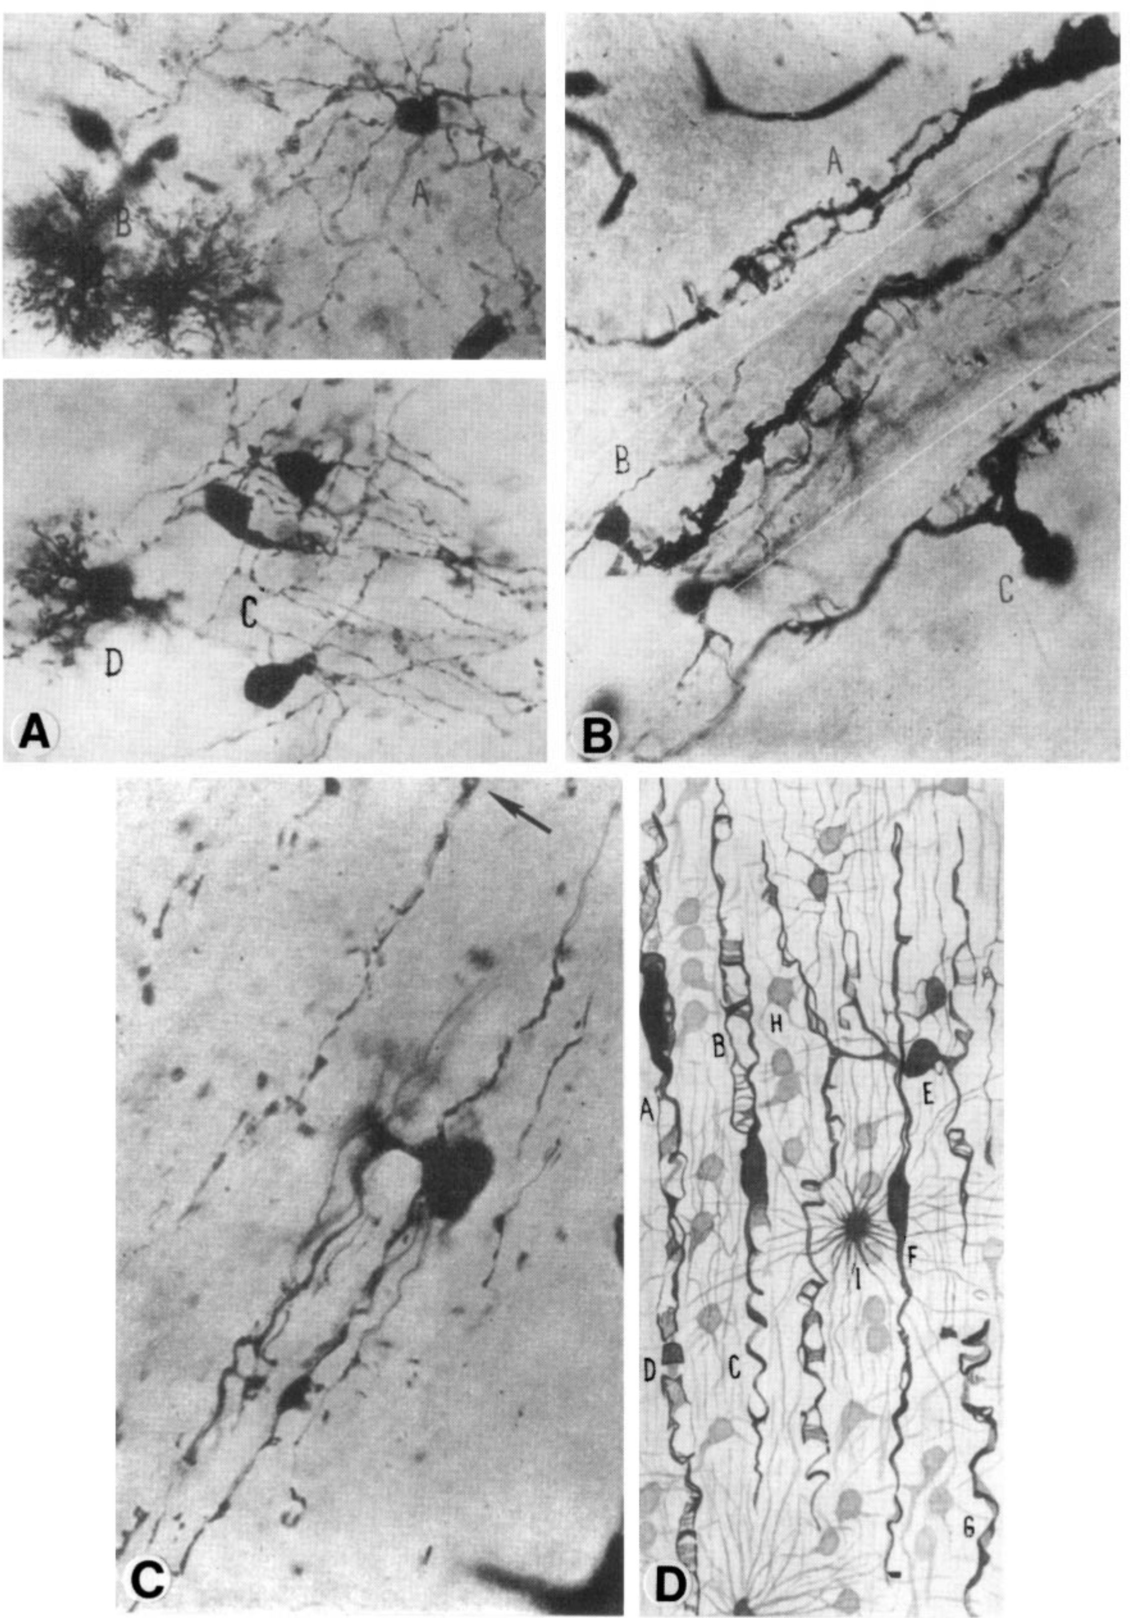

FIG. 2-1. Oligodendrocyte polymorphism. (**A**) Photomicrograph of type I oligodendrocytes from canine cerebral white matter. (*A*) Oligodendrocyte with processes irradiating from cell body; (*B*, *D*) dwarf astrocytes; (*C*) oligodendrocytes with intricate processes. (**B**) Photomicrograph of type III oligodendrocytes from cerebral penduncles. (*B*) Monopolar and (*C*) bipolar cells. (**C**) Photomicrograph of type II oligodendrocyte from cerebellar white matter with parallel processes. Arrow points to ringlike structure; cf. Figure 2-3. (**D**) Oligodendrocytes from feline medullar white matter. (*A,B,F*) Type IV with reticula and rings; (*C,G*) with helices; (*E*) type III; (*H*) type I. [From Rio Hortega (1928), with permission]

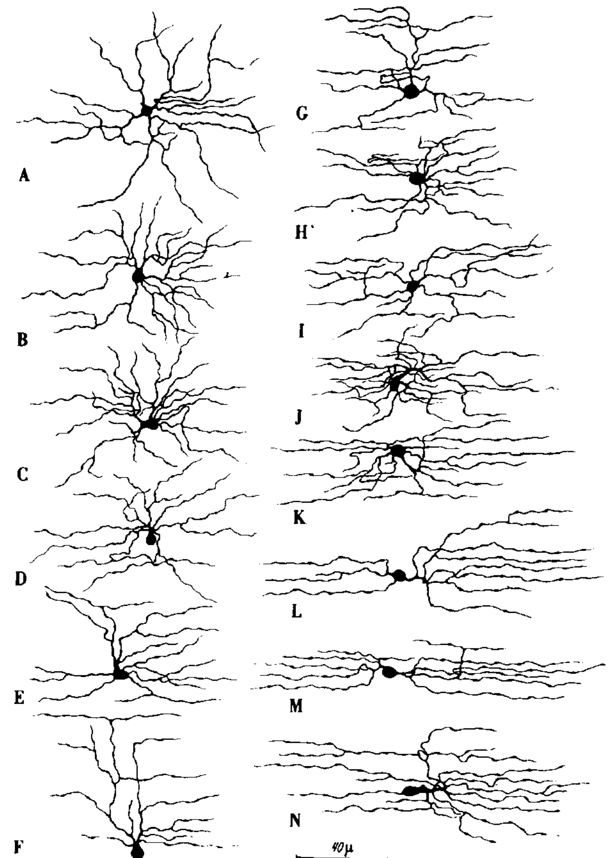

FIG. 2-2. Oligodendrocytes of types I and II. (*A–N*) arranged to show the variation in the orientation of the long, thin processes. Parallel processes are more common for cells located in the white matter but can also be seen in the peripheral plexus. [From Stensaas and Stensaas (1968), with permission.]

and type II (Figure 2-2B). These authors questioned the existence of morphological continuity between all subtypes because no transitional form was observed between types I and II on the one hand, and types III and IV on the other. The employment of a modified version of the metal impregnation technique led to the claim for the existence of a fifth type of OLG (Klatzo, 1952) and to the definition of an elaborate topographical map of OLG-neuronal interconnections (Ogawa et al., 1985).

Visualization of Oligodendrocytes by Intracellular Injection of Dyes. Butt and Ransom (1989) injected optic nerve cells with Lucifer yellow (or horseradish peroxidase). Figure 2-3A illustrates the appearance of cells presumed to be OLGs [later confirmed by electron microscopy (Ransom et al., 1991)]. The authors describe these cells as having 20 to 30 parallel processes that often terminate in loops (arrow in Figure 2-3A) and are connected to the cell somata by a number of fine processes 15 to 30 μm in length. The longitudinal processes are interpreted as corresponding to the tongues of the myelin sheath. This can be better appreciated from a camara lucida drawing (Figure 2-3B). The cells shown in Figure 2-3A and B exhibit a great resemblance to type II OLGs (Figure 2-1C). Notice that processes in Figure 2-1C also terminate in loops (see the arrow). It seems that intracellular injection provides a picture with higher fidelity than metal impregnation. The limitation of the latter technique was stressed by Rio Hortega, who commented on the difficulties of achieving complete penetration. Thus it is likely that the small number of processes emanating from the cell shown in Figure 2-1C is due to poor impregnation. The dye-injection technique also affords the possibility of assessing the number of axons myelinated by a single OLG and the length of a paranode.

That Butt and Ransom (1989) observed only OLGs with a type II morphology may be due to the restricted central nervous system area examined. Given that this methodology appears to provide a clear depiction of cell somata and their processes, it would be instructive to extend such studies to other areas of the central nervous system in order to gather information on the other OLG subtypes. The major drawback to this methodology is that cells have to be independently identified.

Use of Immunocytochemistry to Investigate Oligodendrocyte Morphology. A number of antigenic markers have been exploited to investigate OLGs *in situ* (review by Sternberger, 1984). While the initial work may not have been undertaken with cell morphology as a primary goal, these studies may serve that purpose. For instance, the morphology of myelinating OLGs can be brought to light with an antimyelin basic protein antibody (Ab) or an antiproteolipid protein Ab, as illustrated in Figures 3, 4, and 5 in Sternberger's Chapter 4 in *Oligodendroglia* (1984). But these Abs are of little use in revealing OLG morphology in the mature brain. Thus antigen (Ag) concentration and Ab penetration are two factors that may present practical limitations. Nevertheless, the power of immunological methods resides in the functional information they provide while eliminating the uncertainty of cell identification. Two studies using monoclonal Abs (mAbs) may serve to illustrate the usefulness of the immunocytochemical approach. One concerns the staining of adult spinal cord with the mAb Rip—an OLG-specific mAb (Friedman et al., 1989)—because it yields Golgi-like patterns (Figure 2-4). The authors identified OLG types I to III but were unable to localize type IV OLGs and suggested that they may not be present in the spinal cord. This would be contrary to the finding of Re-

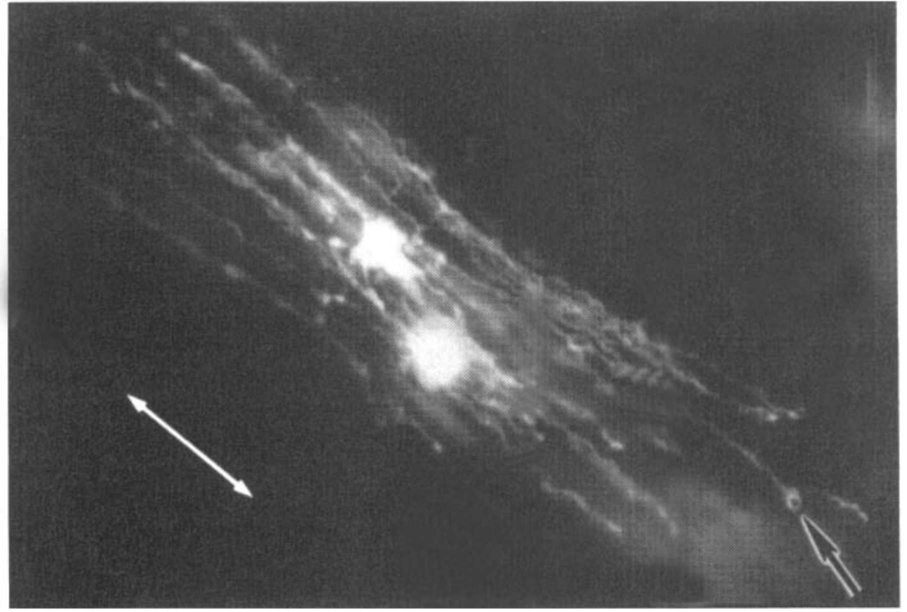

FIG. 2-3. (A) Lucifer yellow-filled oligodendrocytes in the rat optic nerve. These cells have 20 to 30 parallel processes 150 to 200 μm in length exclusively oriented along the long axis of the nerve and connected to the cell body by short thin branches. *Arrow* points to ringlike structures presumed to correspond to paranodal loops. (**B**). Interpretation of the dye-filled image of a presumed oligodendrocyte. **A**, Photomicrograph of horseradish peroxidase-filled oligodendrocytes. Scale bar = 100 μm. **B**, Camera lucida drawing of cell in *A*. **C**, Camera lucida drawing of *A* at higher power (×1250); the cell body and three selected longitudinal processes have been drawn. [From Butt, and Ransom (1989), with permission.]

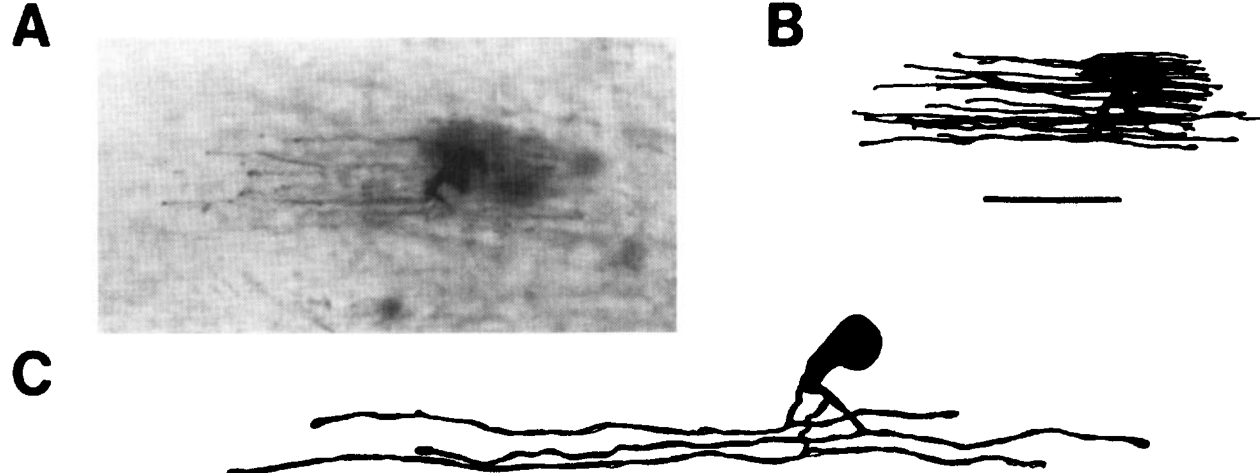

mahl and Hildebrand (1990), who noted that type IV OLGs were restricted to the spinal cord. An alternative explanation could be that type IV OLGs do not carry Rip. Should subtype-specific Ags be discovered, it would not only facilitate enormously the task of identifying the different subclasses but could be instrumental in defining functional properties.

The other example of the use of an mAb to delineate OLG morphology and define the connections between OLGs and other central nervous system components is illustrated in Figure 2-5. mAb Otex1, generated against OLG plasmalemma components (Mori de Moro et al., 1990; D. Arvanitis, G. Mori de Moro, and S. Szuchet, unpublished observations), brings out OLG soma (see the arrowhead in Figure 2-5) and processes in the basis pontis of an adult human brain (Figure 2-5A). The staining is specific; neurons remain clear of reaction products (see the arrows in Figure 2-5A). Intense staining of a group of OLGs and their intricate network of long processes in the cerebellar white matter of a 2-month-old infant is shown in Figure 2-5B. The cell in Figure 2-5A has type I characteristics, whereas in Figure 2-5B types I and II are intermixed. Figure 2-5C depicts an OLG abutting a neuron—a perineuronal satellite. As the number of mAbs directed at OLG-specific Ags increases, and as the newer methods (e.g., confocal microscopy and digital imaging) become accessible for general use, OLG subtypes might be distinguished by their patterns of staining.

The evidence is strong that OLGs constitute a polymorphic family of cells, most of which have a common functional task, the assembly of myelin. The pursuit of other elements that might unite or diversify them remains an interesting proposition. This polymorphism is not restricted to the mam-

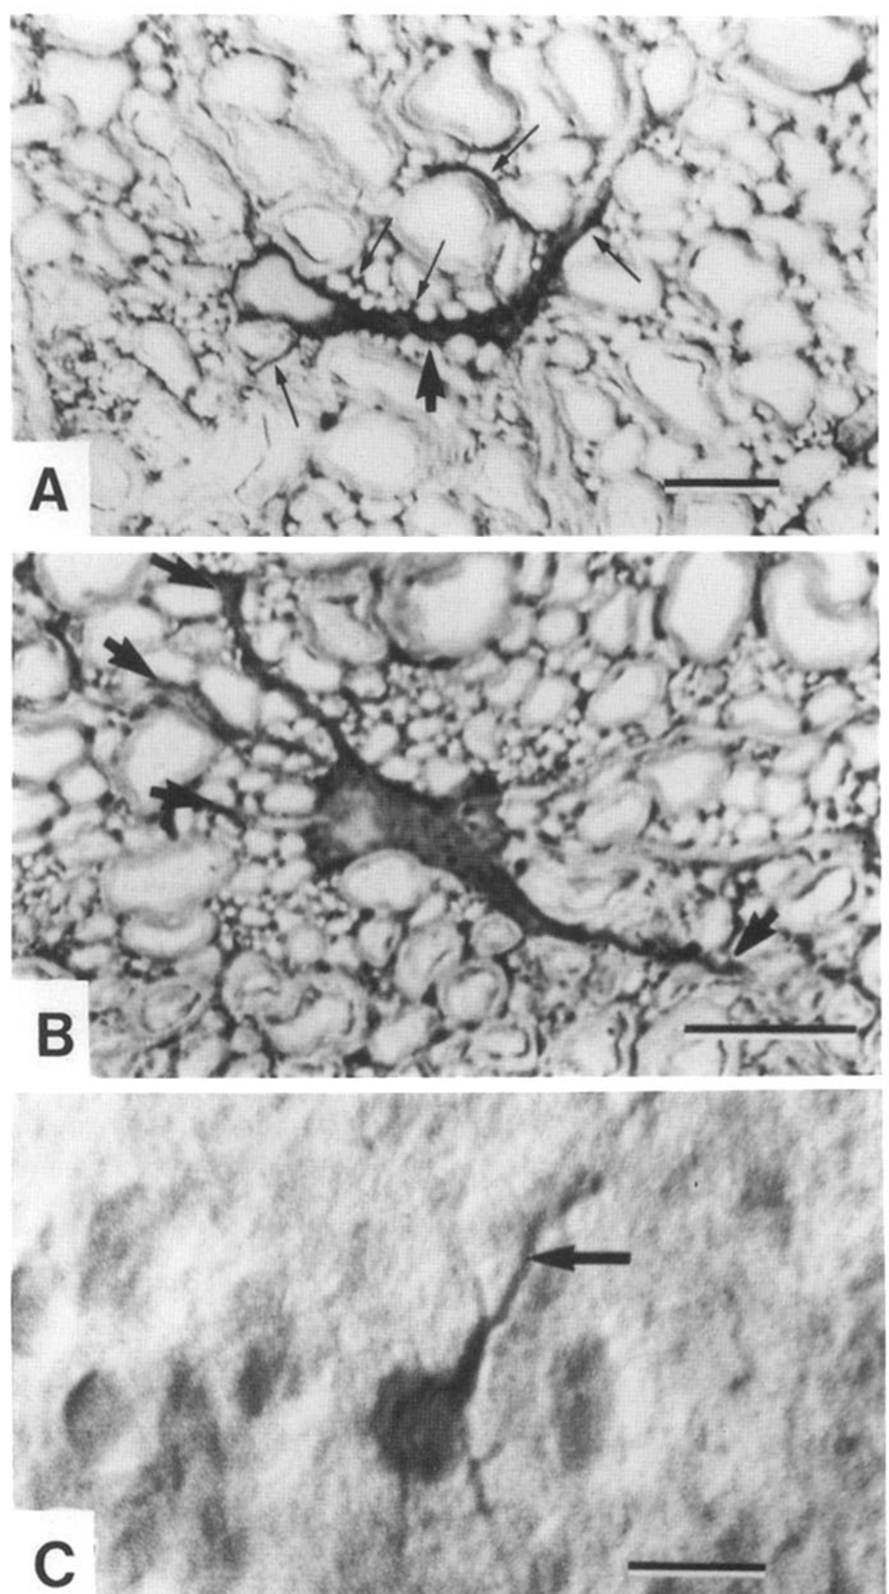

FIG. 2-4. Staining tissue sections with mAb Rip. Rip stains oligodendrocyte somata and their processes in a Golgi-like manner. Scale bar = 10 μm. (A) Oligodendrocytes with long and stout trunk processes that have fine branches. These cells resemble type II oligodendrocytes. (B) Oligodendrocyte with several stout processes (*arrows*) extending directly from the cell body. This cell resembles the type III cells of Rio Hortega. (C) Satellite oligodendrocyte similar to Rio Hortega type I oligodendrocytes.

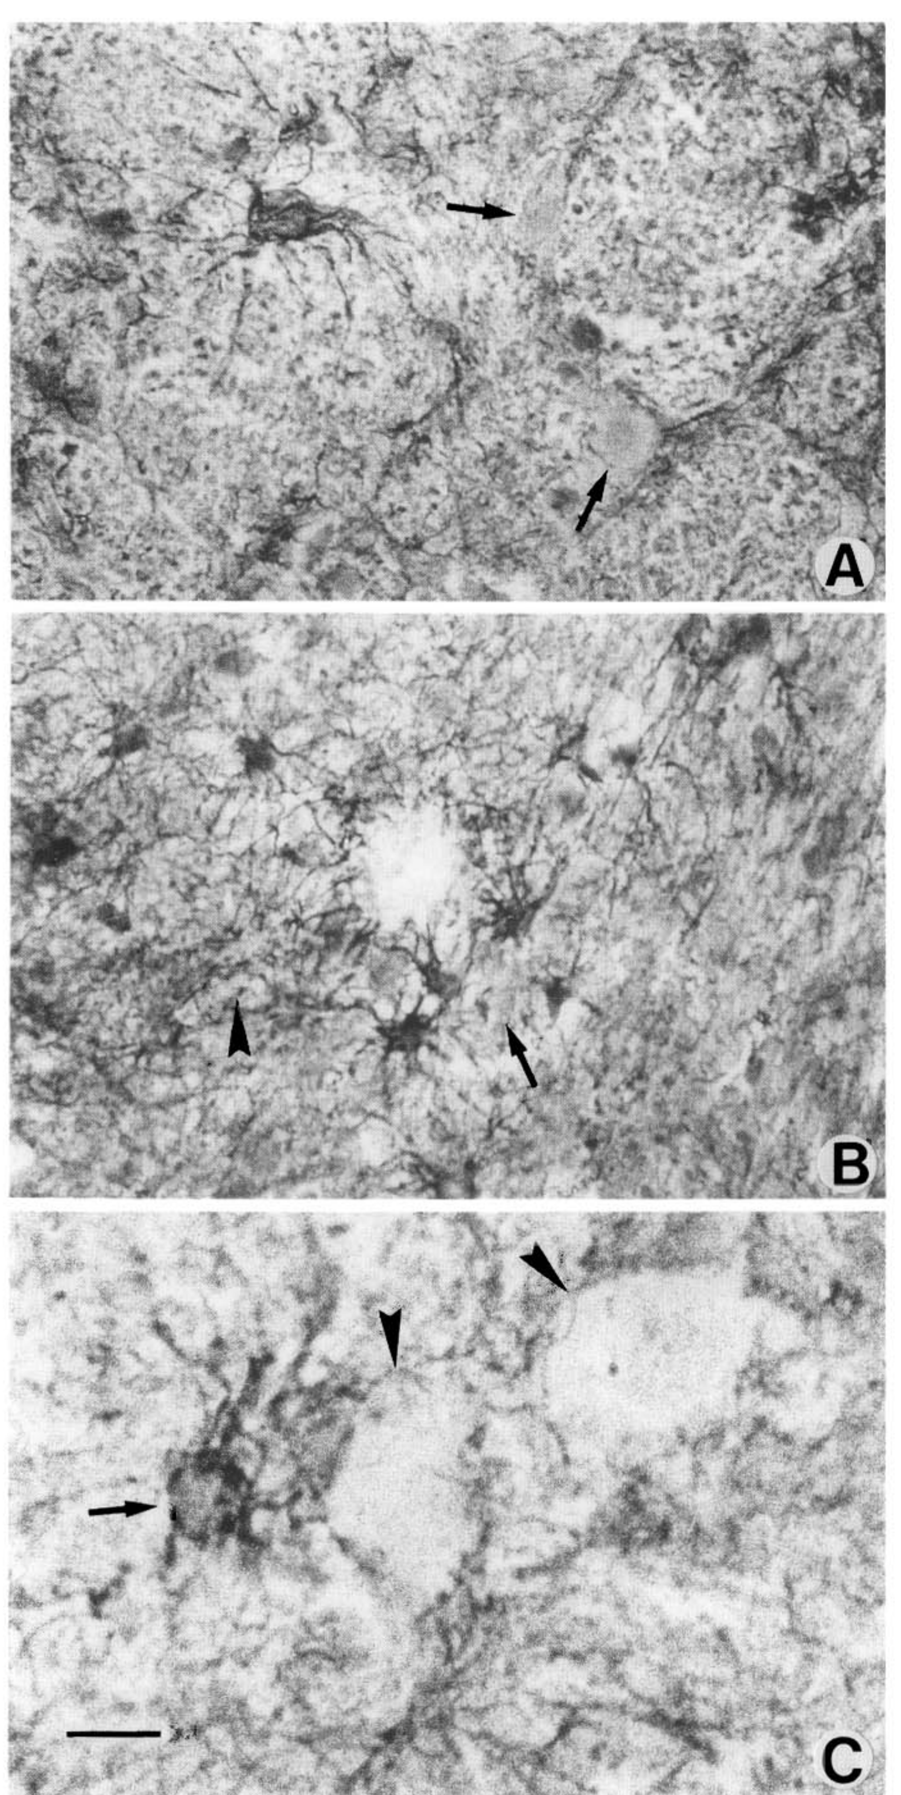

FIG. 2-5. Staining of tissue sections with mAb Otex1. The mAb was generated by injecting mice with live oligodendrocytes. Hybridomas were screened against an oligodendrocyte Triton X-100 extract; only clones that were positive for oligodendrocytes but negative for fibroblasts, astrocytes, and microglial cells were selected, expanded, and cloned. (**A**) Basis pontis from an adult brain. Oligodendrocyte showing strong staining of soma and processes with mAb Otex1. This cell fits the description of a type I oligodendrocyte (*arrowhead*). Neurons are negative (*arrows*). (**B**) Cerebellar white matter of infant. Group of oligodendrocytes organized in rows (*arrow*). Cell somata and process are strongly positive. Note extensive network of processes strongly positive (*arrowhead*). (**C**) Satellite oligodendrocytes in the basis pontis from adult brain. Positive oligodendrocyte (*arrow*) abutting an unstained neuron (*arrowhead*). Arrowhead points to a second neuron. Bar (in *C*) = 32 μm in Figures **A** and **B**; 15 μm in Figure **C**. [D. Arvanitis, G. Mori de Moro, and S. Szuchet, unpublished data.]

malian central nervous system but is found across species. Ramón y Cajal believed that "In the form you meet the whole past and present functioning" (Young, 1991). Expressed differently, structure and function are integrated; one (structure) is a reflection of the other (function). The challenge then is to decipher the meaning of the structural entities.

Ultrastructure

A detailed description of the fine structure of OLGs can be found in textbooks (e.g., Peters et al., 1976, 1991; Haymaker and Adams, 1982), in reviews (e.g., Szuchet and Dumas, 1983; Mugnaini and Walberg, 1964; R. Bunge, 1968; Wood and Bunge, 1984), and in myriad original articles. Thus only a brief summary of salient features is presented here, placing emphasis on aspects of ultrastructure that have not been stressed before.

Viewed by electron microscopy, OLGs appear as moderately dense cells relative to astrocytes. No outstanding differences in the fine structure among OLGs localized in different areas of the central nervous system have been noticed. The nucleus is round or oval and is usually eccentrically located, leaving a large mass of cytoplasm at one pole of the cell. However, sections where the nucleus is surrounded by a thin rim of cytoplasm are also seen. This seems to be the case for interfascicular OLGs. The nuclear content exhibits a slight clumping of chromatin that appears as a rim beneath the nuclear envelope. Stensaas and Stensaas (1968a) have characterized the nuclei of the three types of neuroglial cells from toad spinal cord, that is, astrocytes, OLGs, and microglia. Even at the light microscopic level, the nucleus of each cell type has a distinct appearance. The cytoplasm of OLGs is rich in ribosomes, either free or associated with the endoplasmic reticulum, which is believed to contribute to its electron density. The Golgi apparatus is well developed. Two features—apart from size and electron density—distinguish OLGs from astrocytes and serve to differentiate these two central nervous system cell types. OLGs neither have glycogen granules nor bundles of specific intermediate filaments, such as glial fibrillary acidic protein, which are characteristic of astrocytes. OLGs contain inclusion bodies of various types (Mugnaini and Walberg, 1964).

Ultrastructural Diversity. Electron microscopy reveals another aspect of OLG diversity whose direct relationship to the subtypes described by Rio Hortega have yet to be clarified. Cells identified as OLGs by criteria such as continuity with the outer tongue of the myelin sheath, or characteristic features of intracellular organelles, including the presence of microtubules, were observed to vary in size and cytoplasmic and nuclear densities. Kruger and Maxwell (1966) set out to search for Rio Hortega's polymorphism; instead they found a wide range of cytoplasmic and nuclear matrix densities among interfascicular OLGs from adult rats. They observed a higher abundance of the lighter species than the darker one. All variants were associated with axons, implying no apparent functional distinction concerning myelination. Kruger and Maxwell (1966) found perineuronal OLGs to be more dense than interfascicular OLGs. OLGs in gray matter also exhibited a range of matrix densities, but the preponderant species were the dark cells. Mori and Leblond (1970) and Imamoto et al. (1978) investigated the ultrastructure of OLGs in the corpus callosum of young rats. They too noticed variability in size and electron density among cells that had all the trademarks of OLGs. On the basis of these observations, Mori and Leblond defined three prototypes: light, medium, and dark OLGs distinguished by their decreasing size and increasing cytoplasmic density in the sequence of light to medium to dark (Figure 2-6). The implication of this work is that these different forms represent maturational stages in the development of OLGs and hence functional specialization. It is conceivable that the light OLG, which is observed myelinating axons, is the myelin-making cell, whereas the dark OLG is the myelin-maintaining cell. Such an operational definition can be supported by biochemical evidence (Szuchet et al., 1983, 1986). The notion that OLG fine structure varies as the cell changes its function from making to maintaining myelin is an attractive one. A strong case for this hypothesis was advanced by Parnavelas et al. (1983), who performed a detailed developmental study of the rat. They observed that for the deep cortex and subcortical white matter OLGs underwent a sequential transformation from light to dark forms so that in the mature animal 90% of the cells are of the dark variety. However, these results cannot be generalized to all areas of the central nervous system because in spinal cord white matter medium-type OLGs are encountered even in the adult animal.

The difference in cytoplasmic density in OLGs, which is normally attributed to the richness in ribosomes, cannot be due to the latter because ribosomes are more abundant in light than dark OLGs. The opposite appears to be the case for cisterna of the endoplasmic reticulum and Golgi saccules. The existence of these OLG variants has been amply confirmed (Peters et al., 1991) not only in mammals but in amphibians (Stensaas and Stensaas, 1968b),

FIG. 2-6. teleosts (Diaz-Regueira et al., 1992), and reptiles (Monzon-Mayor et al., 1990) as well.

Three-Dimensional Reconstruction. Classical electron microscopy provides a two-dimensional view of a cell, unless sequential electron micrographs are taken and reconstructed. Stensaas and Stensaas (1968b) undertook such a task and obtained OLG morphologies (Figure 2-7) that reproduce the images of type I and II OLGs as viewed by Golgi-Rio Hortega staining. Recently, Remahl and Hildebrand (1990) performed a detailed analysis of the ultrastructure and three-dimensional conformation of OLGs in developing feline spinal cord and corpus callosum. These areas correspond, respectively, to areas that are myelinated early and late during ontogenesis. Their results—discussed further in the section *The In Vitro Model* . . . —challenge several currently held views.

Two types of cell morphologies were seen in the spinal cord by Remahl and Hildebrand (1990). One is that of a cell connected to the myelin of a single axon (Figure 2-8A). This cell has all the characteristics of a type IV OLG (compare Figure 2-8B with Figure 2-1D). Formally, the relationship of this cell to its myelin sheath (Figure 2-8B) resembles the Schwann cell-myelin association. To the best of my knowledge, this is the first direct electron micrographic confirmation of the existence of such cells. Stensaas and Stensaas (1968a) detected structures—tubular reticulates—with a similar appearance, but they could not identify somata related to them. The other form has processes in continuity with uncompacted cytoplasmic ensheathements (see Figure 2 of Remahl and Hildebrand, 1990). This observation, if confirmed, would call into question the concept that OLGs do not ensheathe axons (R. Bunge et al., 1978; see also the section *The In Vitro Model* . . . later in this chapter.)

In the corpus callosum, the only variants detected fit the most common view of OLGs, that is, a cell associated with many myelin sheaths (Figure 2-9). Such cells would belong to type I or II. Remahl and Hildebrand (1990) made no distinction between them.

OLIGODENDROCYTE SUBTYPES: STRUCTURAL ODDITIES OR FUNCTIONAL ENTITIES?

The notion that OLGs are responsible for making and maintaining myelin rests on solid ground (Peters

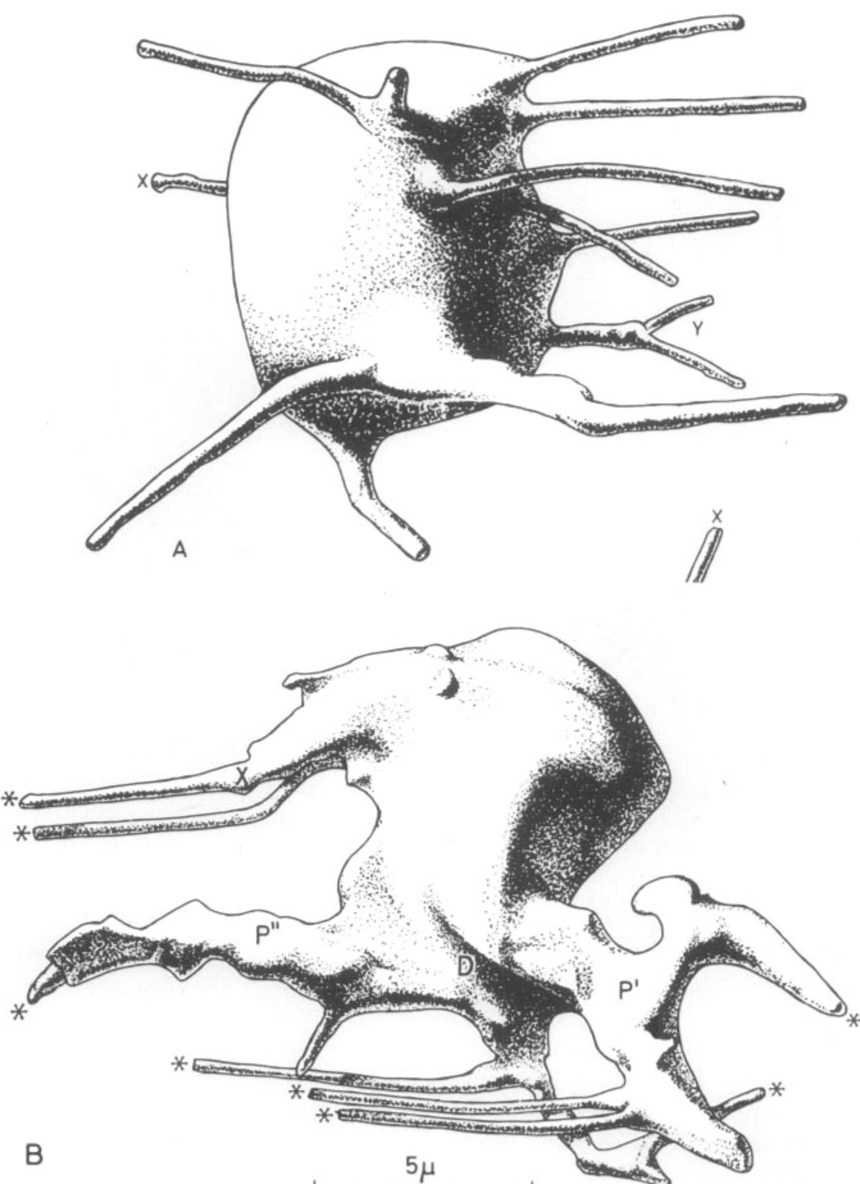

FIG. 2-7 Views of oligodendrocytes reconstructed from serial electron micrographs. (A) and (B) show different cells. These cells resemble Rio Hortega type I or II oligodendrocytes. Processes marked with asterisks are incomplete because they extend beyond the limits of the serial photomicrographs. [From Stensaas and Stensaas (1968), with permission.]

et al., 1991). The evidence is also strong that OLGs constitute a heterogeneous population of cells. This heterogeneity is expressed in more than one way. It is revealed in OLG-axon interactions where associations of 1:1 (type IV OLGs; Figure 2-8) to 1:N (types I or II; Figure 2-9) are formed. This in itself bespeaks functional diversity among myelinating OLGs. First, it was shown by Hartman et al. (1982) that large axons stain more intensely for myelin basic protein than proteolipid protein, whereas the reverse is the case for small axons. Second, compositional differences between myelin isolated from spinal cord and that obtained from the brain have also been described (Norton and Cammer, 1984). Since the spinal cord is populated predominantly by type IV OLGs (Remahl and Hildebrand, 1990), these OLGs may have a different metabolism from those found in the brain. Moreover, myelin changes in composition as it matures, which signifies that OLGs must adjust their metabolism to that effect (Szuchet et al., 1983; Norton and Cammer, 1984). On the surface, these dissimilarities may not seem profound, but their presence foreshadows differences in gene control and expression.

The cell that approaches an axon to commence myelination has an undifferentiated ultrastructure (Remahl and Hildebrand, 1990). The issue is whether the fate of such a cell to become a given OLG subtype, for example, type IV, is predetermined by genetic programming and/or is influenced by its microenvironment. For instance, is the cross-talk between neurons and OLGs in the spinal cord different

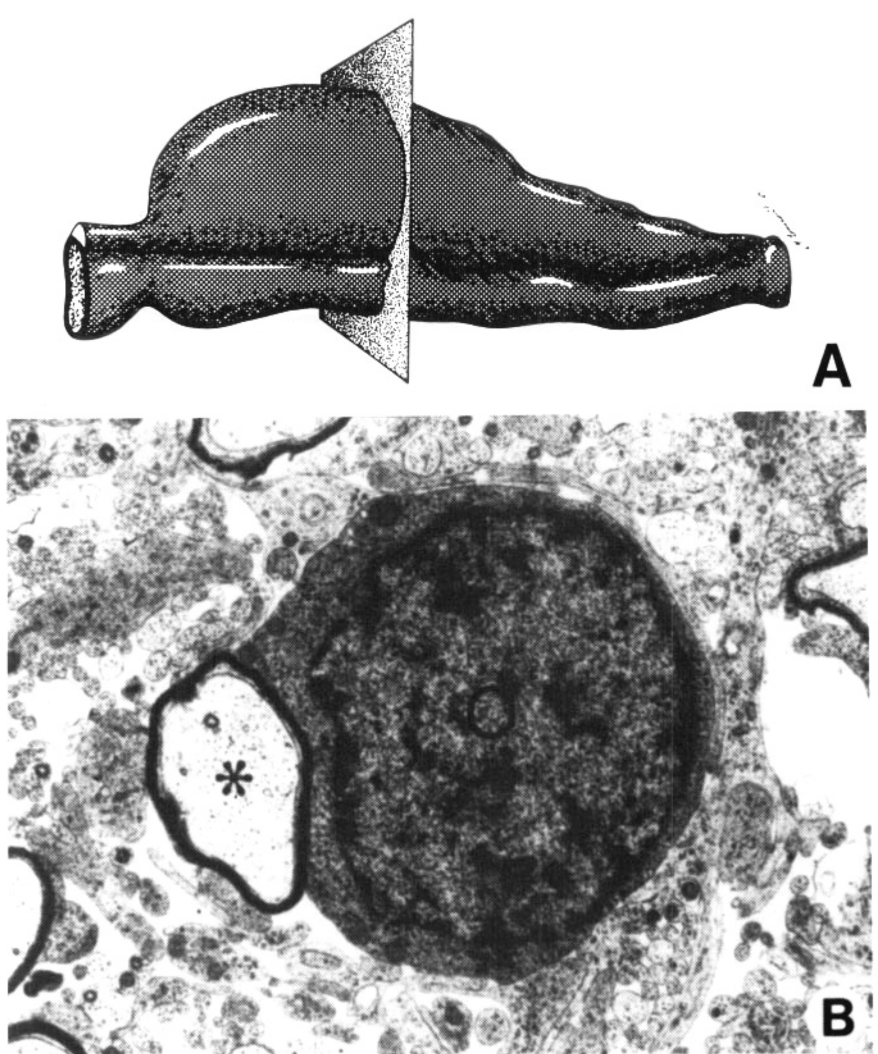

FIG. 2-8. Oligodendrocyte from feline spinal cord of 47-day-old fetus. (A) An M-type glial unit, which includes one axon. Note the close relation between the perikaryon and the myelin sheath that extends along the whole cell body. (B) This electron micrograph corresponds to the transverse plane marked on Figure 8A. O indicates the nucleus of the oligodendrocyte linked to one axon with an M-sheath (*). [From Remahl and Hildebrand (1990), with permission.]

from that in the brain? It is a common finding that the thickness of a myelin sheath is related to the girth of the axon it invests; the thicker the axon, the thicker the myelin. Indeed, the same OLG may produce myelin of different thickness according to the size of the axons it wraps (Friedrich and Mugnaini, 1983; but see Remahl and Hildebrand, 1990). It has been suggested that the total amount of myelin synthesized by an OLG is relatively constant (Blakemore, 1981). These findings have been used to argue that it is the neuron that regulates myelination (Blakemore, 1981; Waxman and Sims, 1984; Waxman, 1987). These concepts have been challenged by recent observations, indicating that the amount of myelin an OLG assembles may be primarily determined by its type and only indirectly by the size of the axon (Remahl and Hildebrand, 1990).

There are OLGs that are not involved in the myelination process under normal circumstances, for example, perineuronal OLGs. One may wonder what it is they do. It has been shown that such OLGs have the potential to myelinate and seem to do so under pathological circumstances (Ludwin, 1984), but this is not their normal function. Moreover, in species where central nervous system regeneration takes place (e.g., fish), Diaz-Regueira et al. (1992) found no perineuronal OLGs in the medulla. The suggestion has been made that satellite OLGs may specialize in tending a specific type of neuron, for example, Purkinje cells (Monteiro, 1983). Should this be the case, it would imply a greater OLG diversity than what is currently envisioned. In a similar vein, the complexity of processes displayed by "perivascular" OLGs (see Figure 18 in Rio Hortega, 1928) makes it difficult to conceive that they have no specific function, even though they may not actually abut a capillary. In the adult mammal, there is strong evidence for the existence of a thin sheet of astrocytic membrane interposed between the OLG and the blood vessel (Mugnaini and Walberg, 1964; Nagash-

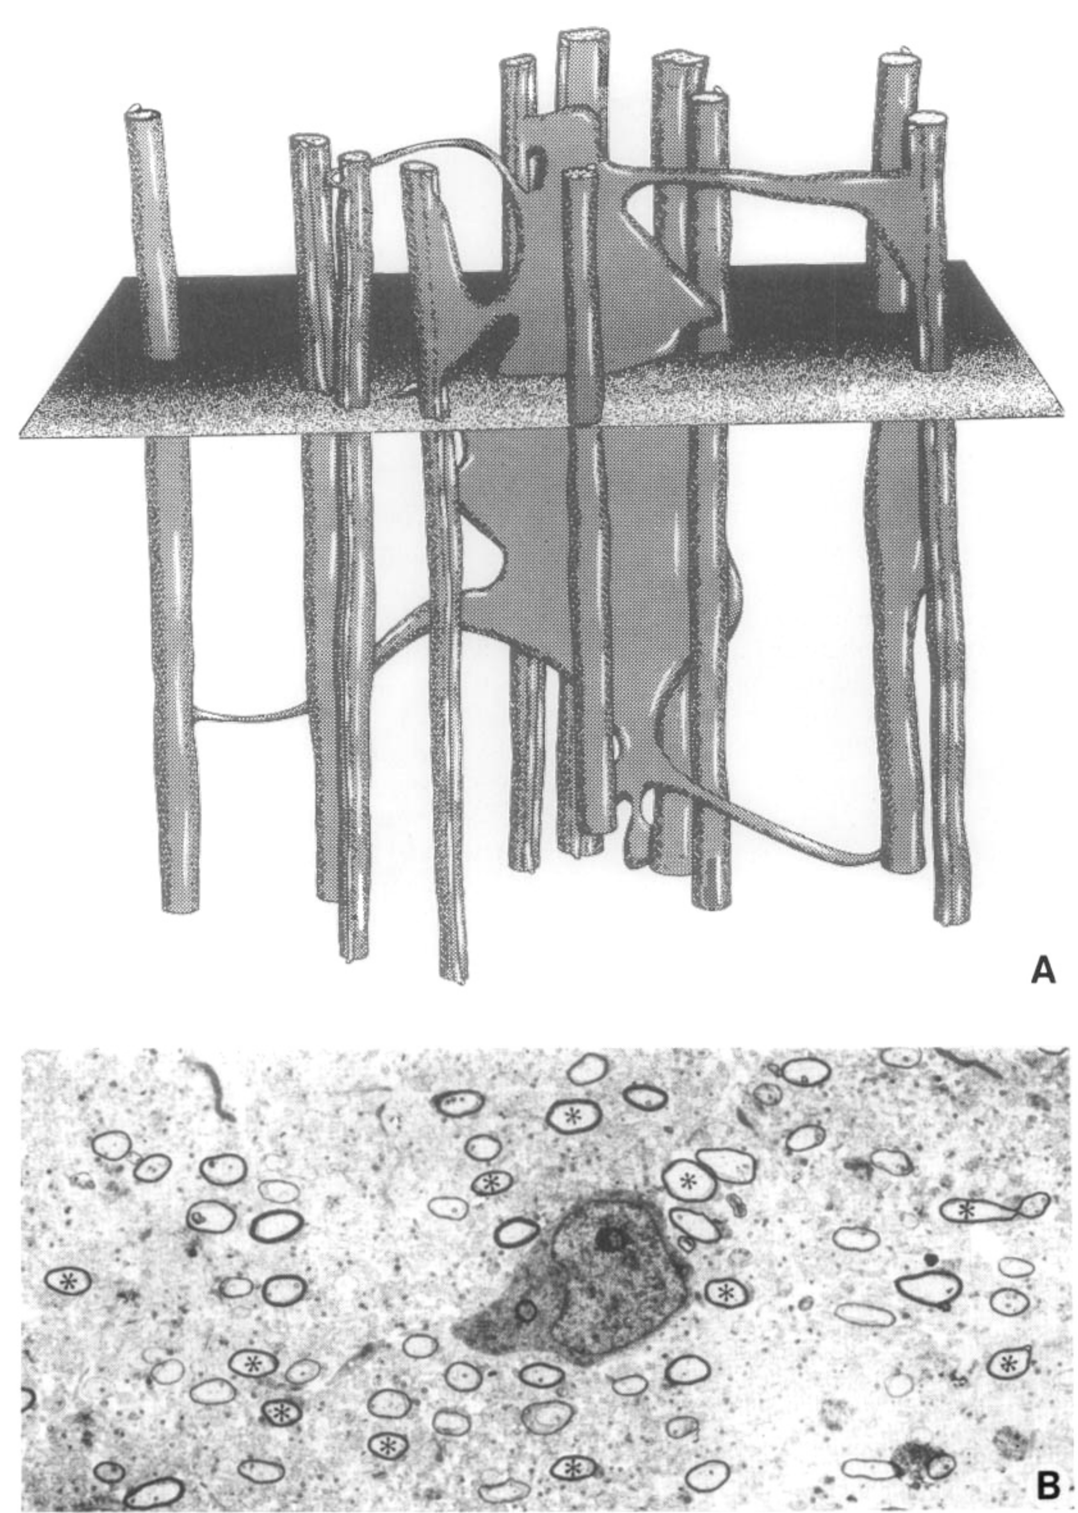

FIG. 2-9. Oligodendrocyte from feline corpus callosum, 21 days postnatal. (A) An M-type glial unit including 11 axons. (B) This picture corresponds to the transverse plane marked on Figure 9A. The 11 axons are indicated by asterisks and the oligodendrioglial cell body (O) and nucleus are clearly seen. [From Remahl and Hildebrand (1990), with permission.]

ima, 1979). This appears to be the case for other species as well (Long et al., 1968). Unfortunately, we know very little about what the function of these so-called "perivascular" OLGs might be.

It would be outside the scope of this chapter to discuss the function of OLGs in a general sense (see Kuffler et al., 1984; Peters et al., 1991). My intent here has been to point out that morphology may be only one factor that differentiates the various OLG subtypes; function may be the other. Functional specialization of OLG subtypes could perhaps account for what now stand out as discrepancies. For example, using freeze-fracture electron microscopy, Massa et al. (1984) found tight junctional complexes between OLGs; no gap junctions were detected. These results are in line with findings *in situ* (Massa and Mugnaini, 1982) but are at variance with the observations of Blankenfeld et al. (1993), who described electrical and dye coupling of OLGs as they mature. Butt and Ransom (1989) obtained similar results for OLGs from the optic nerve. The electrophysiology of OLGs is also marred by some controversy (e.g., see Soliven et al., 1988, 1989; Kettenmann et al., 1991). There may be a single explanation for this, and it is that different OLG subtypes were being examined. Thus it may prove rewarding to characterize OLGs from specific areas of the central nervous system. Suggestions have been advanced that astrocytes from different central nervous system regions may have distinctive properties (Ransom, 1991).

THE *IN VITRO* MODEL: MORPHOLOGY OF IMMATURE VERSUS MATURE OLIGODENDROCYTES AND FUNCTIONAL IMPLICATIONS

OLGs can be isolated from neonates as typified by the procedure of McCarthy and de Vellis (1980) or they can be isolated from young but myelinated animals as exemplified by the method of Szuchet et al. (1980a) (see also Shahar et al., 1988). OLGs can be maintained as pure cultures (Szuchet et al., 1980) or as a mixed population of cells (review by Pfeiffer, 1984). These cultures afford a unique opportunity to investigate the effect of the microenvironment and/or other cell types on OLG morphology and ultrastructure.

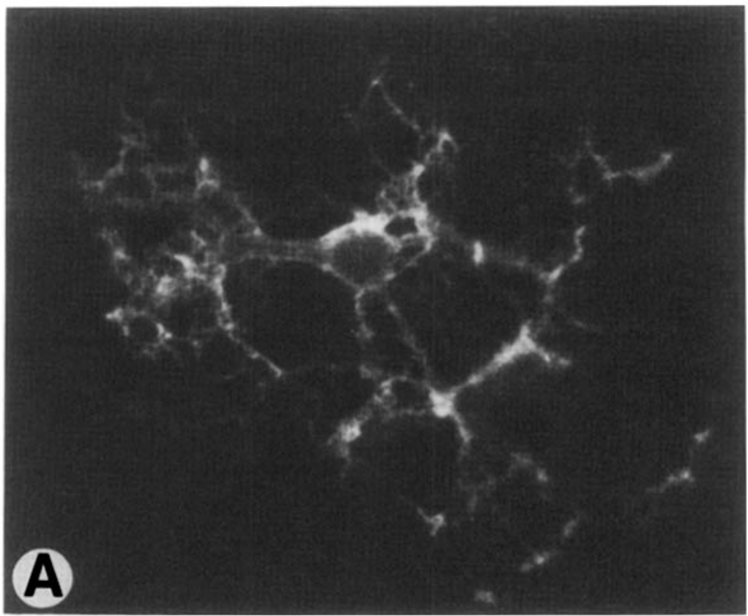
The Immature Oligodendrocyte

Perusal of the literature reveals that OLGs isolated from rat or mouse neonates have a distinct morphology (Figure 2-10A) that appears to be independent of the details of methodology or the medium utilized. The cell soma is either round or polygonal and has three to five stout processes emerging directly from the body, each of which produces an expansive network of fine processes and membranes. Such cells stain positively for galactocerebroside—an OLG-specific marker—and express myelin components. The immature cells exhibit little or no similarity to the OLGs illustrated in Figure 2-1; however, the cell in Figure 2-10A shows a striking resemblance to the mossy OLGs (compare Figure 2-10A with Figure 2-10B) described by Ramón-Moliner (1958). The mossy cells can be found in white and gray matter with essentially no morphological distinction between them. The mossy cell has not been detected in mature animals. Ramón-Moliner speculates that it represents an immature form of OLG capable of differentiating into a myelin-forming cell, as evidenced by the acquisition of parallel processes (see Figure 4 in Ramón-Moliner, 1958). Immature OLGs, when kept in long-term cultures, assemble myelinlike membranes (e.g., Bradel and Prince, 1983), which supports the view held by Ramón-Moliner (1958).

Kuhlmann-Krieg et al. (1988) attempted to correlate the morphology and ultrastructure of cells isolated from 10-day-old mice with surface antigens that define successive stages of OLG differentiation. They concluded that the *in vitro* morphology may be more a reflection of metabolic states than differentiation states. The recent findings of Remahl and Hildebrand (1990) indicate that the biochemical differentiation of OLGs, as assessed by the expression of myelin-specific components, precedes the morphological differentiation. Thus the cell that begins myelination appears as morphologically undifferentiated. Only after some myelin has been deposited does the cell acquire the ultrastructure that is its trademark.

The Mature Oligodendrocyte

OLGs (isolated from postmyelination brains) adhered to a suitable substratum and kept in culture (Szuchet et al., 1983; Yim et al., 1986) essentially free of other cell types acquire morphologies that resemble those seen *in situ* (Figure 2-11). Illustrated in Figure 2-11 are morphologies that approximate OLGs of types I, II, and III of Rio Hortega (1928). This phase-contrast micrograph was taken from a 90-day-old culture. Such cultures can be thought of as "myelinating" because they contain a large number of multilamellar membranous structures (Szuchet et al., 1986). The most striking feature of Figure 2-11 is the presence of long parallel processes not unlike the processes OLGs extend along nerve fibers (compare Figure 2-11 with Figure 2-2). The connotation



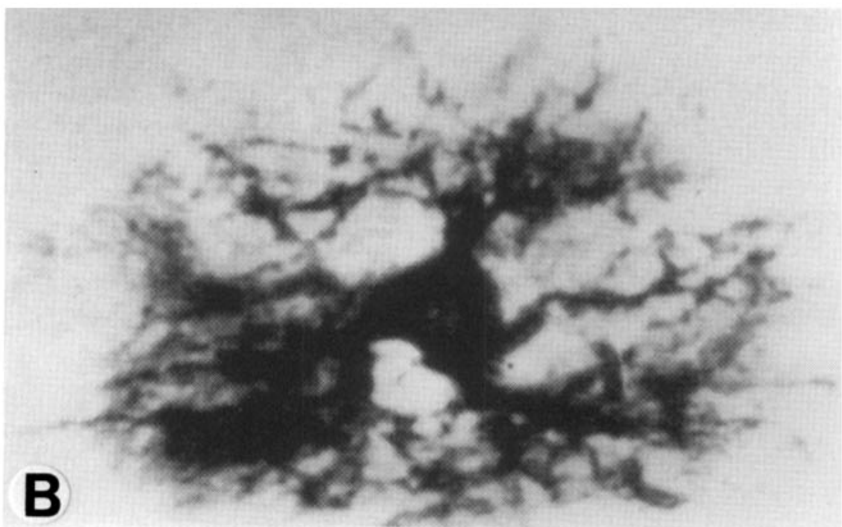


FIG. 2-10. Immature oligodendrocytes. (A) Oligodendrocyte in a culture of dissociated 19- to 21-day fetal rat brain, after 22 days in culture, stained by immunofluorescence with antigalactocerebroside. [From Pfeiffer (1984), with permission.] (B) Mossy type of oligodendrocyte. Golgi-Rio Hortega stain. [From Ramón-Moliner (1958), with permission.]

here is that this seems to constitute an intrinsic property of OLGs poised for myelination and does not require the presence of an axon. However, most of these OLGs should have been in contact with an axon prior to their isolation, which leads to two alternative possibilities: (1) OLGs need a signal from axons to differentiate morphologically, but they need it only once; and (2) the signal is always required, but substratum can function as a surrogate. The second possibility appears to be the most likely (Szuchet et al., 1983; Yim et al., 1986).

The different OLG morphologies developed *in vitro* can be appreciated better when the cells are outlined immunocytochemically (Figure 2-12) than when live cells are examined. In Figure 2-12A, a type I OLG is shown with processes radiating from the cell and branching out to cover an extensive area. One may speculate that this OLG might have occupied a perineuronal or "perivascular" position. Figure 2-12B depicts a number of closely apposed OLGs with all the morphological characteristics of type II. These cells could clearly claim a place among the interfascicular OLGs. An example of a type III OLG is portrayed in Figure 2-12C. Three sturdy processes emanate from the cell body, two of which bend in a direction perpendicular to the initial course to run parallel to one another. Two monopolar cells are illustrated in Figure 2-12D; they should correspond to type IV OLGs. These cells have been stained with an antimyelin basic protein Ab, which attests to their identity as OLGs. As is the case *in situ*, the predominant classes are types I, II, and III (possibly in this order). Type IV is rarely found. This agrees with the observation of Remahl

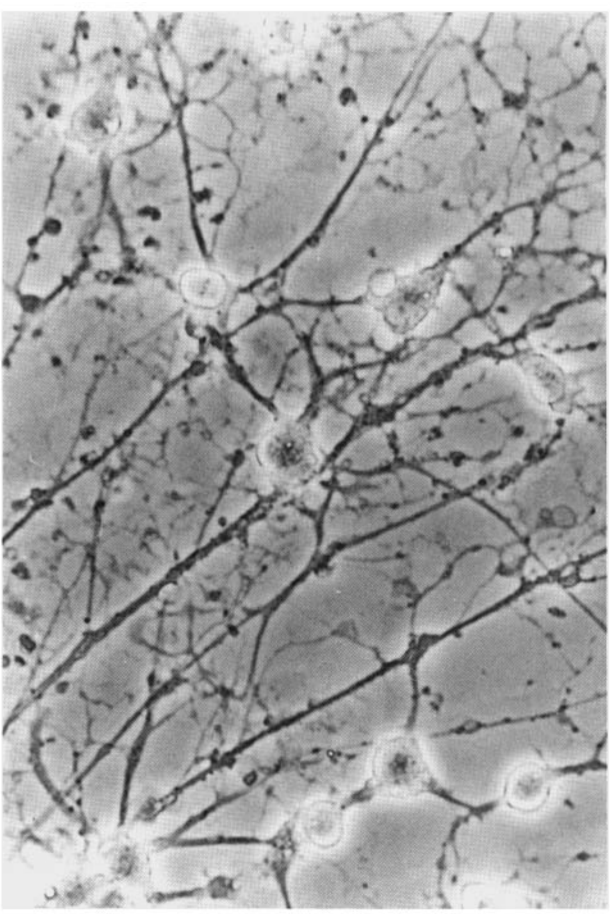

FIG. 2-11. Phase-contrasted micrograph of live oligodendrocytes; 90-day-old culture. Of note are the long, parallel processes and the varied morphology of the cells. [S. Szuchet, unpublished data.]

and Hildebrand (1990), who only detected type IV OLGs in the spinal cord. The cultures described originate from brain white matter. It is interesting that all these morphologies are observed. The fact that this type of heterogeneity has not been described in cultures of neonates could be taken to indicate that neurons may have a say in the manner in which OLGs develop, and this becomes imprinted in the cells. So even after they have been separated from the inducer they reenact whatever morphology they had *in situ*. This line of reasoning leads one to speculate that each of these morphologies might be endowed with distinct functional characteristics.

The ultrastructure of cultured OLGs has been investigated by a number of laboratories (e.g., Wollmann et al., 1981; Gonatas et al., 1982; Massa et al., 1984; Kuhlmann-Krieg et al., 1988). The consensus is that the ultrastructure of the cultured cells parallels closely the characteristics of the *in situ* cells. Wollmann et al. (1981) examined OLGs isolated from 3- to 6-month-old lamb brains. They observed that the freshly isolated cells were more electron-lucent than cells from the same animal examined in tissue sections. The authors attributed this to a dedifferentiation of the isolated cells. However, after adhesion to a substratum and extension of processes, OLGs acquired characteristics similar to those seen *in situ*. Variation in electron density as described by Mori and Leblond (1970) was seen with a predominance of the medium OLG.

The studies of Wollmann et al. (1981) were extended by Massa et al. (1984) to encompass three experimental stages: (1) freshly isolated OLGs; (2) OLGs maintained in a nonadhered state; and (3) adhered OLGs. Each of these stages could be equated operationally to myelin-maintaining OLGs, dedifferentiated OLGs, and myelin-making OLGs (Szuchet et al., 1983; Szuchet and Yim, 1984; Yim et al., 1986). These studies placed particular emphasis on cell-cell interactions as viewed by freeze-fracture electron microscopy. Only the remarkable features will be presented.

In thin section, the freshly isolated OLGs appeared to be moderately electron-dense; the cytoplasm contained the usual complement of intracellular organelles. Of salience were intracellular vacuoles with electron-dense membranes and blebs on the plasmalemma that mark sites of adhesion to neighboring cells. Intramembrane particles revealed by freeze-fracture electron microscopy resembled qualitatively and quantitatively those found in OLGs *in situ* (Massa and Mugnaini, 1982). Where two OLGs came in close apposition, there was an enrichment of intramembrane particles. Gap junction and tight junction particles occurred frequently, with the former predominating. Fragments of blebs that have the orthogonal arrays characteristic of astrocytic membranes were often associated with the gap junctions. This finding was interpreted as showing that *in situ* OLGs were coupled to astrocytes (Massa and Mugnaini, 1982).

The nonadhered OLGs showed round cell somata without processes. The cytoplasm contained numerous microtubules. Overall the cells resembled OLGs described in the brains of young mammals (Mori and Leblond, 1970). Nonadhered OLGs were apposed to one another, but no junctional particles were detected.

Upon adhesion to a substratum, OLGs differentiate morphologically by extending numerous cylindrical and flattened processes. OLGs were examined after 1 to 5 weeks in culture. In thin section, outstanding features were a prominent Golgi apparatus, an abundance of microtubules, and electron-dense bodies. Coated pits were frequently observed on the

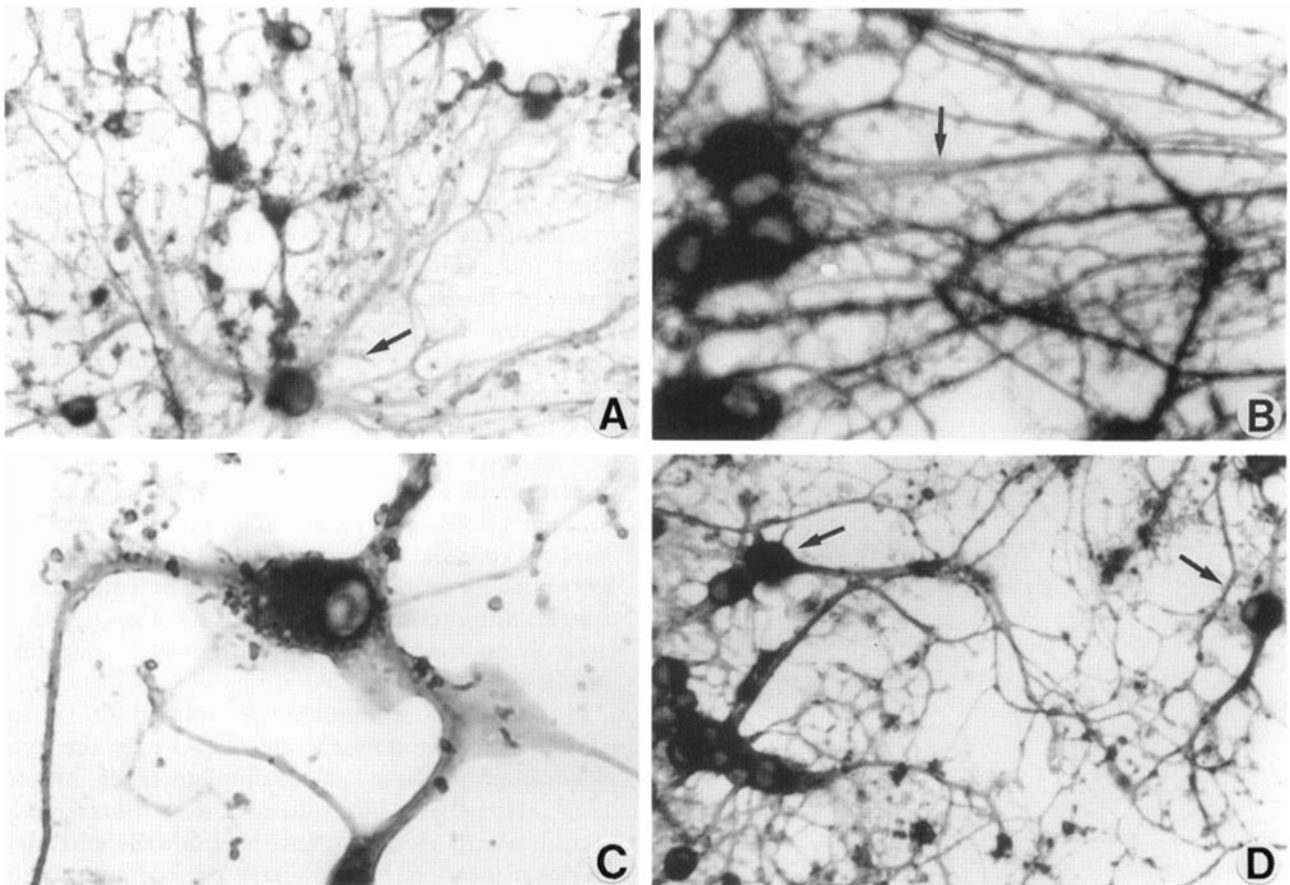

FIG. 2-12. Micrographs of cultured oligodendrocytes stained with antimyelin basic protein. (**A**) Oligodendrocyte with 4 to 6 hefty processes emerging from the soma (*arrow*) and branching out. This cell resembles type I oligodendrocyte. (**B**) Group of closely apposed oligodendrocytes with parallel processes (*arrow*), resembling type II oligodendrocyte. (**C**) Oligodendrocyte with morphological features of type III. This oligodendrocyte has three sturdy processes emanating from the cell body. (**D**) Type IV oligodendrocyte. *Arrows* point to cells with a type IV morphology.

plasma membrane that apposed the substratum and other OLGs. Freeze-fracture electron microscopy revealed globular and elongated particles distributed on the P and E faces. Linear arrays that resembled the peculiar tight (occluding) junctions of myelin (Schnapp and Mugnaini, 1978) were often seen. Their numbers increased with time in culture. In contrast, no gap junctions were found. These observations suggest that OLGs require an input from astrocytes for the synthesis of gap junctions.

EXTRINSIC AND INTRINSIC FACTORS THAT MODULATE OR DETERMINE OLIGODENDROCYTE MORPHOLOGY

Trophic Factors

Our knowledge of the cues that guide OLGs in their path toward differentiation is meager at best. That a neuronal input is required stems from the now classical experiments of Fulcrand and Privat (1977), who showed that, in early stages of OLG differentiation, they seem to require an interaction with neurons. However, the nature of this interaction has never been defined. *In vitro,* hormones (de Vellis, 1990) and growth factors (Raff and Lillien, 1988; Hart et al., 1989; McKinnon et al., 1990; McMorris et al., 1990) influence the differentiation of OLGs; some of them appear to be operative *in situ* as well. Paradoxically, because OLGs maintain their phenotype in the absence of other central nervous system cell types and behave permissively with respect to substrata, their requirements for biochemical and morphological differentiation have been difficult to establish. This is to be contrasted with Schwann cells, whose trophic wants are proving to be easily decipherable (R. Bunge et al., 1986) because they lose their phenotype in the absence of (1) an input from neurons, (2) an extracellular matrix, and (3) certain nutrients.

The *in vitro* changes in OLG morphology induced by growth factors have been documented by several laboratories (e.g., Kachar et al., 1986; Sontheimer et al., 1989). For example, platelet-derived growth factor (PDGF) can drive the cells reversibly from a stellate to a bipolar morphology (McKinnon et al., 1993). These authors also found that cell shape was associated with the expression of specific markers. A similar observation was made by Warrington and Pfeiffer (1992), using tissue blocks. This, however, has not been the experience of Kuhlmann-Krieg et al. (1988).

Effect of Substratum on Morphological Differentiation

Cell-substratum adhesion plays a crucial part in the cascade of events that control growth or turn on and consummate a differentiation program. For those cellular systems that amass an extracellular matrix, the latter fulfills a complex set of functions that include (1) facilitating access to growth factors, (2) controlling the activity of proteases-protease inhibitors involved in tissue modeling-remodeling, and (3) providing a host of adhesion molecules and other ligands (review in Hay, 1991). The importance of an extracellular matrix for the differentiation of Schwann cells and for myelination in the peripheral nervous system has been clearly established (M. Bunge and Bunge, 1986; R. Bunge et al., 1989). Extracellular components such as proteoglycans and adhesion molecules have been shown to be present in the central nervous system (Herndon and Lander, 1990; Rauch et al., 1991, 1992; Grumet et al., 1993). For example, polyclonal and monoclonal Abs against astrochondrin—a newly characterized chondroitin sulfate from brain (Streit et al., 1993)—have been shown to inhibit formation of processes of mature glial fibrillary acidic protein-positive astrocytes on laminin or type IV collagen. No direct information is available as to what role, if any, extracellular matrix components play in the development of OLGs and in central nervous system myelination. Circumstantial evidence suggests that they may play a major part. Yim et al. (1993) have demonstrated that the adhesion of OLGs to substratum induces the synthesis of both peripheral, for example, displaceable by heparin, and integral heparan sulfate proteoglycans. The peripheral heparan sulfate proteoglycans are incorporated asymmetrically into the plasma membrane, leading to its polarization; their removal prevents cell adhesion. These authors suggest that heparan sulfate proteoglycans are key molecules in the morphological differentiation of OLGs.

In vitro, the signal for the biochemical and morphological differentiation of postmyelination OLGs arises from adherence to an adequate substratum (Szuchet et al., 1983; Szuchet and Yim, 1984; Yim et al., 1986). Isolated OLGs kept in a nonadhered state, for example, plated on tissue culture plates, form aggregates (see the section *The In Vitro Model* . . .) but fail to extend processes or differentiate biochemically (Vartanian et al., 1986; Yim et al., 1986). OLGs behave selectively toward substrata. They adhere poorly on collagen, laminin, and fibronectin, characteristics that set them apart from Schwann cells and neurons. Native vitronectin is not effective either, but exposure of the cryptic heparin-binding domain of vitronectin by urea denaturation converts it into an acceptable substratum (Schirmer et al., 1993). Ovadia et al. (1984) reported that when OLGs adhered to an extracellular matrix generated by bovine corneal endothelial cells, they underwent proliferation and differentiation. Laminin and other extracellular matrix components were believed to be responsible for this effect. However, OLGs were loosely attached and tended to form clusters when plated on purified laminin. These authors also found collagen to be ineffective. Cardwell and Rome (1988a, 1988b) found an extracellular matrix derived from glial cells lysed with H_2O (astroglial matrix) to be an effective substratum for rat OLGs. Ovine OLGs express their myelinogenic repertoire when plated on a polylysine-coated surface in the presence of 20% horse serum (Szuchet and Yim, 1984). Schirmer et al. (1994) have purified a novel, heparin-binding glycoprotein from horse serum, which they have termed GRASP—glycine-rich adhesion serum protein. When GRASP is coated on plates precoated with polylysine, it promotes the differentiation of OLGs in DMEM alone, that is, in the absence of serum. However, when growth factors, hormones, and metals are added to the DMEM, OLGs prosper as well and even better than with 20% horse serum. Schirmer et al. (1994) speculate that an integrinlike molecule and heparan sulfate proteoglycans are involved in the GRASP mode of action.

Influence of Cell-Cell Interaction on Oligodendrocyte Morphology

No systematic studies have been performed that define the influence astrocytes and/or neurons might have on OLG morphological development.

Neuronal Input: How Is It Manifested? In the peripheral nervous system neuronal input is expressed by direct physical contact between the Schwann cell

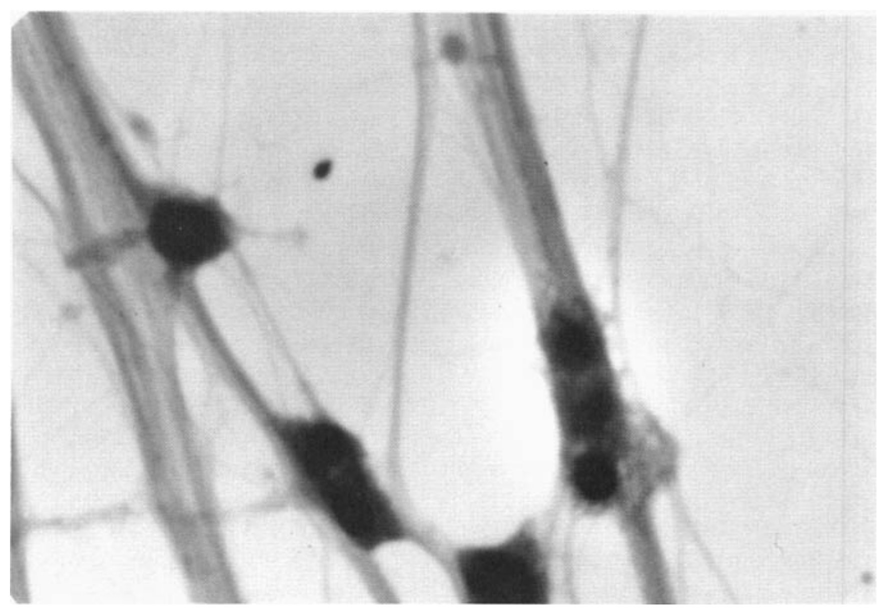

FIG. 2-13. Adherence of oligodendrocytes on dorsal root ganglion neurites. Isolated ovine oligodendrocytes were added to rat dorsal root ganglion cultures. Oligodendrocytes adhered preferentially on the neurites and formed rows of closely apposed cells, not unlike interfascicular oligodendrocytes. Noteworthy is the fact that cells have extended processes along the neurites. Oligodendrocytes that stayed on the substratum (collagen) formed clumps. No processes emanated from the latter cells. Stained with toluidine blue. (P. Wood and S. Szuchet, unpublished observations.]

and the neuron. I have already alluded to the work of Fulcrand and Privat, wherein it was noted that OLGs need a neuronal input. These experiments do not indicate whether physical contact between the two cell types is needed or whether the influence is transmitted via a secreted factor. Also, OLGs appear to do well *in vitro* in the absence of neurons, even when isolated as precursor cells, which lends an element of uncertainty to the notion of neuronal influence. That OLGs choose to adhere to neurons over another substratum can be inferred from the results of adding isolated OLGs to neuronal cultures. OLGs adhere preferentially to the neurite and develop morphologically by extending processes along the nerve fibers (Figure 2-13). In contrast, OLGs that remained on the substratum (collagen) formed clumps without extending processes. These results point strongly to a surface interaction between the two cell types.

Astrocytic Influence. *In situ,* OLGs and astrocytes are coupled by gap junctions (Massa and Mugnaini, 1982). As mentioned above, freshly isolated OLGs carry the remnants of such junctions. However, once OLGs adhere and develop in culture in the absence of astrocytes, they no longer seem to express the component necessary for the formation of gap-junctional complexes (Massa et al., 1984). These observations can be interpreted as indicating that OLGs need an input from astrocytes in order to assemble gap junctions. That OLGs appear to be able to accomplish their myelination repertoire without gap junctions suggests that the latter subserve a function that may not be directly related to the formation of myelin. Alternatively, the *in vitro* environment compensates for the lack of junctions.

Oligodendrocyte-Oligodendrocyte Interaction. This topic is brought up only for the sake of completeness. We know little to nothing on this issue. *In situ,* OLGs align in rows of closely apposed cells; tight junctions have been found between these cells (Massa and Mugnaini, 1982). Again, remnants of these particles are detected in the freshly isolated OLGs (Massa et al., 1984). Significantly, *in vitro* tight junctions are also formed between the cells organized in rows, not unlike the situation *in situ.* The manner in which these junctions contribute to the structural organization and/or function of OLGs remains an open question.

Cultured OLGs secrete constitutively to the medium six sulfated glycoproteins and chondroitin sulfate proteoglycans that are temporally modulated. Their functions remain unknown. It is tempting to speculate that some of them might have an autocrine/paracrine function (Szuchet and Yim, 1990).

CONCLUSIONS AND PERSPECTIVES

In this chapter I have described OLG morphology and ultrastructure with particular emphasis on (1) the morphological polymorphism of OLGs, and (2) establishing a link between polymorphism and function. The data presented set the presence of polymorphism on firm ground. It is manifested *in situ* as well as *in vitro;* it is detected by a variety of techniques. Thus neuroscientists will have to come to

grips with the notion that OLGs are not a homogeneous population of cells; rather, they are organized in subtypes with selected locales for each of them. It required roughly sixty years for the findings of Río-Hortega to be revindicated. The elegant work of Remahl and Hildebrand established the first link between morphology and functional specialization. Clearly this only marks the beginnings. Efforts should now be directed toward isolating OLGs from specific regions and characterizing their biology.

It is conceivable that the biology of a type IV OLG bears more resemblance to that of a Schwann cell than to a type II OLG. However, type IV OLGs are not Schwann cells: they lack a basal lamina, which is essential for the proper function of Schwann cells. Since the assembly of a basal lamina by the Schwann cell is under the control of the neuron, it implies that the lines of communication between type IV OLGs and neurons are different from those utilized by the Schwann cell-neuron connection. Superimposed on the morphological heterogeneity is an ultrastructural heterogeneity. This may be the result of changes in the metabolism associated with making and maintaining myelin. Another area that needs to be addressed is that of the satellite OLGs, that is, perineuronal and "perivascular." Are they keepers of the microenvironment? Such studies, however, may have to await new technological advances before meaningful attempts can be made.

The factors that influence OLG growth and differentiation remain largely undefined. In particular, we know very little of what the neuron does. When and how do these two cell types talk to each other? Does the neuron have a say about whether an OLG will become type IV or type II, or is this information imprinted in the genetic makeup of the cell? What part does the microenvironment play? If the assertions of Remahl and Hildebrand are correct, then type IV OLGs appear before type II. This would indicate that the fate of an OLG subtype may be established ontogenically. Tissue culture, if interpreted with due reservations, could well serve as the vehicle for addressing many of the outstanding questions.

I would like to thank my coworkers past and present for their contributions. I am grateful to Mr. P.E. Polak and Mr. L. Hill for their help with the illustrations and in preparing this chapter, respectively. Work from my laboratory included in this chapter was supported by grants from the National Institutes of Health, National Multiple Sclerosis Society, United Leukodystrophy Foundation, the Brain Research Foundation of the University of Chicago, and by gifts from Ms. E. Stein, Mr. N. Cohn, and the Lucille P. Markey Charitable Trust.

3 Basic biology of the Schwann cell

RICHARD P. BUNGE AND CRISTINA FERNANDEZ-VALLE

Essentially everywhere in the peripheral nervous system glial cells are interposed between nerve cell bodies and fibers and the surrounding nonneural tissues. Within sensory and autonomic ganglia, these cells assume perineuronal positions as satellite cells. Within the ganglia of the enteric plexuses of the gut, glial cells encase the neuronal aggregates in a manner similar to the disposition of astrocytes of the central nervous system. Within the peripheral nerve trunk, they ensheathe all nerve fibers, whether myelinated or unmyelinated. These glial cells of the peripheral nerve trunks, the cells of Schwann, are the subject of this chapter.

Schwann cells provide housing for axons within peripheral nerves. Part of this housing function is the formation of an interface between the neural tissue and surrounding tissues. Thus, around each axon-Schwann cell unit there is invariably a basal lamina, which delineates the border with adjacent connective tissue components. This arrangement allows a peripheral nerve to contain considerable amounts of connective tissue to provide the requisite physical strength and yet retain within it tubular channels for the delicate nerve fibers. In addition to this function, Schwann cells form myelin sheaths along the larger nerve fibers. The deposition of myelin in segments influences the location of sites allowing ionic current passage in the enclosed nerve fiber; this partitions the axolemma, concentrating certain ion channels at the intervening nodes of Ranvier. This positioning allows saltatory conduction of the nerve impulse, which increases the velocity of nerve conduction as much as 100 times. Beyond these basic functions, the Schwann cell is able to respond to nerve injury by helping to remove cellular debris, by facilitating the process of remyelination, and by promoting nerve fiber regeneration. For almost a century the presence of Schwann cells in the peripheral nerve trunk and their absence in the central nervous system has been considered a primary factor in the differences in regenerative capacity between these two tissues (see the translation of Rámon y Cajal's *Degeneration and Regeneration of the Nervous system,* first published in 1913–1914; Cajal, S. R., 1991).

SCHWANN CELLS IN EARLY DEVELOPMENT

Source of Schwann Cells

In the past decades it has been stated that Schwann cells derive from two structures transiently present during embryogenesis: the neural crest and the placodes of the head region (Harrison, 1924). Recent observations on chick/quail chimeras indicate that, with the exception of the olfactory placode, neural crest cells may be the source of all glial cells in the peripheral nervous system, including the Schwann cells of the peripheral nerve trunks, the satellite cells of sympathetic and parasympathetic ganglia, and the distinctive glial cells of the enteric ganglia. According to these observations, in most ganglia receiving placodal contributions only the nerve cells themselves are of placode origin, with all attending glia deriving from neural crest (for review, see LeDouarin et al., 1991; Ziller and LeDouarin, 1993). Schwann cells appear at a very early stage during the development of peripheral nerve and migrate outward along axonal fasciculi as the peripheral nerve trunks form (Tennyson, 1965; Webster and Favilla, 1984). Schwann cell populations for the ventral nerve roots are provided from neural crest cells migrating ventrally along the lateral aspect of the neural tube. There is no evidence that Schwann cells can be derived from other cell types subsequent to the embryonic period (Asbury, 1975). Schwann cells, however, maintain the ability to dedifferentiate following injury, and to proliferate, providing additional Schwann cells for the regenerative process (see below).

Early Stages of Development

In the earliest stages of peripheral nerve development, outgrowing bundles of axons are accompanied by small numbers of Schwann cells, which position themselves between the axons and the surrounding connective tissue, providing a partial intervening basal lamina (Ziskind-Conhaim, 1988). As will be discussed below, the number of Schwann cells

is influenced by contact with the axons and, as their numbers increase, they migrate interiorly into the axon bundles (Asbury, 1967; Webster, 1993). As the increasing numbers of Schwann cells isolate smaller and smaller bundles of axons, each axon-Schwann cell unit begins to acquire its own basal lamina, and thus the interior of the nerve begins to acquire its connective tissue components. Schwann cells related to the larger axons capable of inducing myelination position themselves along the axon length (R. Bunge et al., 1989). They then elongate and engulf a specific length of axonal domain prior to forming a membranous scroll around the axon that becomes the multilamellar myelin sheath. Smaller axons that are destined to remain unmyelinated induce their associated Schwann cells to differentiate into an ensheathing cell. These Schwann cells specialize in harboring one or several small-diameter axons within furrows on their surface. Eventually these axon-Schwann cell units are interspersed with collagen fibrils, fibroblasts, and ingrowing blood vessels. Groups of axon-Schwann cell units then become surrounded by a complex sleeve of flattened cells comprising the perineurium. This perineurial sheath forms a tissue/nerve barrier, which effectively excludes extraneural proteins from the internal regions of the nerve. It has recently been established that perineurial cells are recruited from the regional fibroblast population, and are not modified Schwann cells as had sometimes been suggested (M. Bunge et al., 1989a). The extracellular components within the perineurium compose the endoneurium. Both the Schwann cells and the fibroblasts contained within the endoneurium are known to contribute to the substantial amount of connective tissue deposited between each of the axon-Schwann cell units and which gives peripheral nerves their characteristic cord-like consistency (Obremski et al., 1993a, 1993b; reviewed in M. Bunge, 1993). Surprisingly, about one-third of the protein in a peripheral nerve is collagen. After enough Schwann cells have been generated to both myelinate the larger axons and ensheathe the smaller axons, the number of Schwann cells within the peripheral nerve trunk becomes stabilized (Asbury, 1967). As the nerve subsequently grows, new segments of myelin are not added to accommodate the growth; instead each of the myelin segments is extended in length so that myelin segments that may be 200 μm in length when first formed may subsequently reach 1000 μm in length.

Markers for Schwann Cell Subtypes

Both myelinating and ensheathing Schwann cells arise from a common precursor, which is recognized in the rat by the expression of S-100 (a calcium-binding protein) at embryonic day 15 to 16 and the O4 antigen (a sulfatide) 1 to 2 days later (reviewed in Jessen and Mirsky, 1991). Myelination of largest diameter axons begins soon after birth in rats and is followed by myelination of progressively smaller axons just prior to or at the same time as ensheathement of the smallest axons begins, 2 to 3 weeks after birth (Martin and Webster, 1973; Webster et al., 1973). The two subtypes of Schwann cells can be identified by the expression of various components (Mirsky and Jessen, 1984). Myelin-forming Schwann cells express myelin-associated glycoprotein, protein zero, myelin basic protein, peripheral myelin protein 22, and lipids comprising the myelin sheath, including galactocerebroside (Politis et al., 1982; Quarles, 1983; Martini and Schachner, 1986; Jessen et al., 1987a; Lemke and Chao, 1988; Mitchell et al., 1990; Snipes et al., 1992). Ensheathing Schwann cells do not express the myelin proteins, but instead synthesize glial fibrillary acidic protein, neural cell adhesion molecule, nerve growth factor receptor, and the adhesion molecule, L1, and share the expression of galactocerebroside with myelinating Schwann cells (Jessen et al., 1985; Daniloff et al., 1986; Martini and Schachner, 1986; Mirsky et al., 1986; Jessen et al., 1987b). As will be discussed later, expression of these characteristic components is determined by interactions with the axon. Throughout maturity it is generally accepted that both subtypes of Schwann cells remain plastic in their ability to respond to the axon and to redifferentiate into either a myelinating or ensheathing Schwann cell following injury in which axonal contact is first lost, and then reestablished as nerve fibers regenerate (Weinberg and Spencer, 1975; Aguayo et al., 1976a, 1976b).

SCHWANN CELL SUBTYPES: ENSHEATHING AND MYELINATING

The majority of ensheathing Schwann cells are associated with the unmyelinated afferent axons of dorsal root ganglion neurons and the unmyelinated efferent sympathetic axons of autonomic ganglia, such as the superior cervical ganglion. The diameter of these axons generally ranges from 0.4 to 1.0 μm, although unmyelinated axons up to 3.0 μm may sometimes be found (Webster, 1993). Unmyelinated axons are found dispersed among myelinated axons in peripheral nerves and are more often found in closer proximity to small-diameter myelinated axons than to large-diameter myelinated axons. Because the ensheathement provided by nonmyelinating

Schwann cells is not necessary to allow nerve fiber conduction, the function of the ensheathing cell remains to be adequately explained. Myelinating Schwann cells are associated with the larger axons of somatic, sensory, and certain autonomic neurons. In mammals, these axons range in size from 1 to 15 μm. It is generally held that those axons in the peripheral nervous system that attain a diameter of greater than 1 μm have the capacity to induce myelin formation by related Schwann cells (Matthews, 1968; Friede, 1972).

The Ensheathing Schwann Cell

Schwann cells related to unmyelinated nerve fibers provide ensheathement via membranous indentations on the surface of the Schwann cell, which typically provide residence for individual axons in separate troughs (Figure 3-1A). This basic pattern of ensheathment of unmyelinated nerve fibers is substantially modified, however, in several parts of the body (R. Bunge, 1968). In the olfactory nerve, Schwann cells provide common ensheathement for small bundles of axons, often several dozen small diameter axons being contained within one ensheathing trough. Substantially modified ensheathing cells (also known to be of neural crest origin) are found in the myenteric plexus of the gut wall (Jessen and Mirsky, 1983). Here, the nonneuronal cells provide communal ensheathement, both for nerve cell bodies and for nerve processes without separation of these neural elements by intervening cytoplasmic extensions and without the deposition within these neural aggregates of connective tissue. In these regions, a basal lamina surrounds the entire miniature ganglion containing both nerve fibers and nerve cell bodies in a manner reminiscent of the glial limitans of the central nervous system. These glial cells of the enteric plexus contain an intermediate filament with immunocytochemical characteristics of the intermediate filaments within astrocytes (Jessen and Mirsky, 1983). Thus, in their manner of ensheathement, their relationship to basal lamina and their cytoplasmic constituents, they resemble astrocytes of the central nervous system.

The Myelinating Schwann Cell

In the process of forming a segment of myelin, the Schwann cell first elongates along the axon to engulf a domain of axolemma approximately 200 μm in length (Webster, 1993). During this time, the axon is separated away from other axons and a unitary relationship between the Schwann cell and this length of axon is established (Figure 3-2 and 3-3). Direct observations of Schwann cells undertaking myelination in tissue culture indicate that Schwann cells actively compete for axonal domain during this period (Figure 3-3). Evidence has recently been presented that the formation of myelin is accomplished by one lip of the encircling Schwann cell process slipping under the other and pushing itself forward assertively along the axon surface (R. Bunge et al., 1989) (Figure 3-4). As it pushes aside the overlying Schwann cell cytoplasm, the advance of this inner lip draws out a spiral of membrane, which, with compaction, will become the definitive myelin sheath. According to this view, the spiral is formed by the progressive advancement of the inner lip of the Schwann cell over the axon surface rather than by advance of the outer lip of the spiraled Schwann cell cytoplasm over its outer surface.

Upon compaction of the spiraled membranes with myelin sheath maturation, some Schwann cell cytoplasm is retained external to the compacted lamellae as an external cytoplasmic collar, and internally as the internal cytoplasmic collar (Figure 3-1B). Evidence has been presented (reviewed in Griffin et al., 1993) that the retention of cytoplasm in this inner collar is related to its content of myelin-associated glycoprotein. Cytoplasm is also retained in periodic interruptions of membrane compaction within the myelin segment; these regions of cytoplasmic retention are termed Schmidt-Lanterman clefts.

The arrangement of the Schwann cell membranes that form the myelin sheath at the node of Ranvier (Figure 3-2A) is remarkably systematic. The layers of spiraled membrane separate to enclose a small amount of cytoplasm, and this terminal loop is applied to the surface of the axolemma near the node of Ranvier (Figure 3-2B). Successive layers of Schwann cell membrane terminate similarly, the most external layers terminating nearest the nodal region, and the innermost layers of the spiral terminating farthest from the node. This alignment of terminal loops adjacent to the nodal axolemma is termed the perinodal apparatus. The specialized contacts that develop between these loops and the underlying axolemma have been described in detail (Schnapp and Mugnaini, 1975). The cytoplasm within the terminal loops is rich in microtubules, considered important for transport of materials from the external cytoplasmic collar of Schwann cell cytoplasm to the internal collar adjacent to the axon. Nodes of the larger nerve fibers are much more complex than the nodes shown in Figure 3-2, which are formed around an axon only 1.5 μm in diameter. In the paranodal regions of the largest nerve fibers, compact myelin in the paranodal region is fluted,

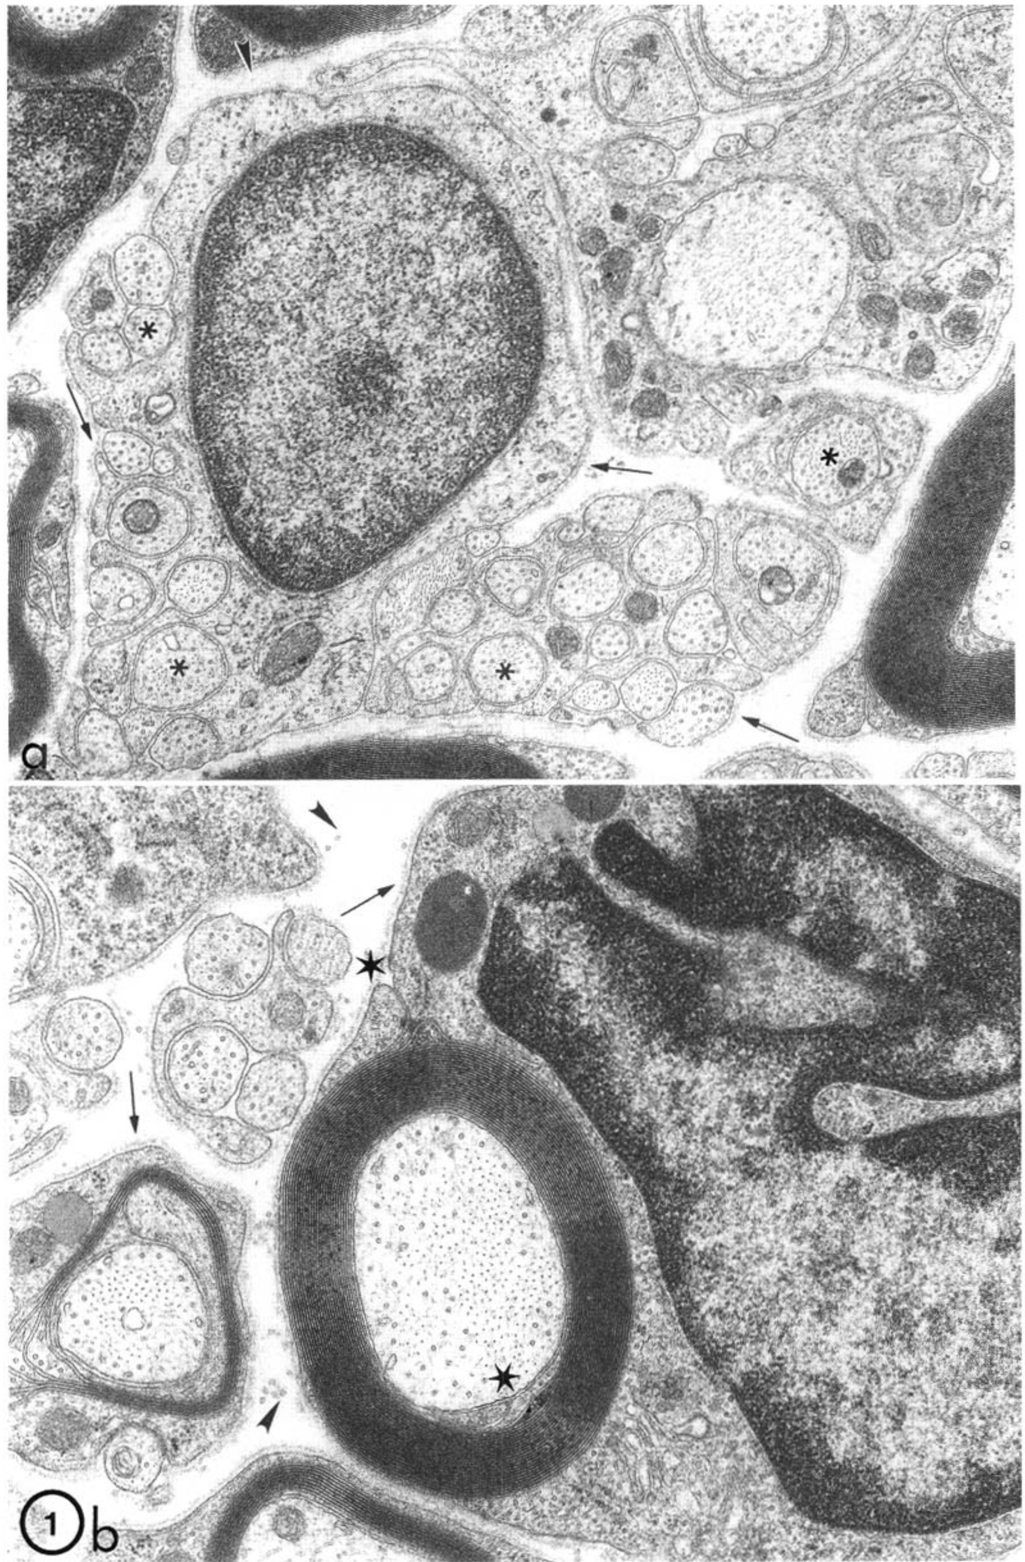

FIG. 3-1. (A) Ensheathing Schwann cell. A Schwann cell with its nucleus is seen in the center of the micrograph performing the function of ensheathement. A number of axons (some marked *) have been individually surrounded by the cytoplasm of this Schwann cell and separated from each other. The entire unit, consisting of a Schwann cell and its related axons, is surrounded by a basal lamina (*arrows*). Collagen fibrils (*arrowheads*) are located outside the basal lamina. Additional ensheathed axons are present to the right. Only the cytoplasmic processes of the Schwann cell and its basal lamina are seen. ×25,000. (B) Myelinating Schwann cell. A Schwann cell with its nucleus is seen in this micrograph performing the function of myelination. The enclosed axon is surrounded by multiple layers of compacted, specialized Schwann cell membrane forming the myelin sheath. The beginning of this spiral at the inner mesaxon and the termination of the spiral at the outer mesaxon are marked (*stars*). Also note the mitochondria, Golgi apparatus, and lysosome in the cytoplasm. The entire unit is surrounded by basal lamina (*arrows*), and collagen fibrils (*arrowheads*) occupy the extracellular space between adjacent myelinated axons. An adjacent smaller axon is at an early stage of myelination. ×25,000. [Courtesy of Dr. Mary Bartlett Bunge.]

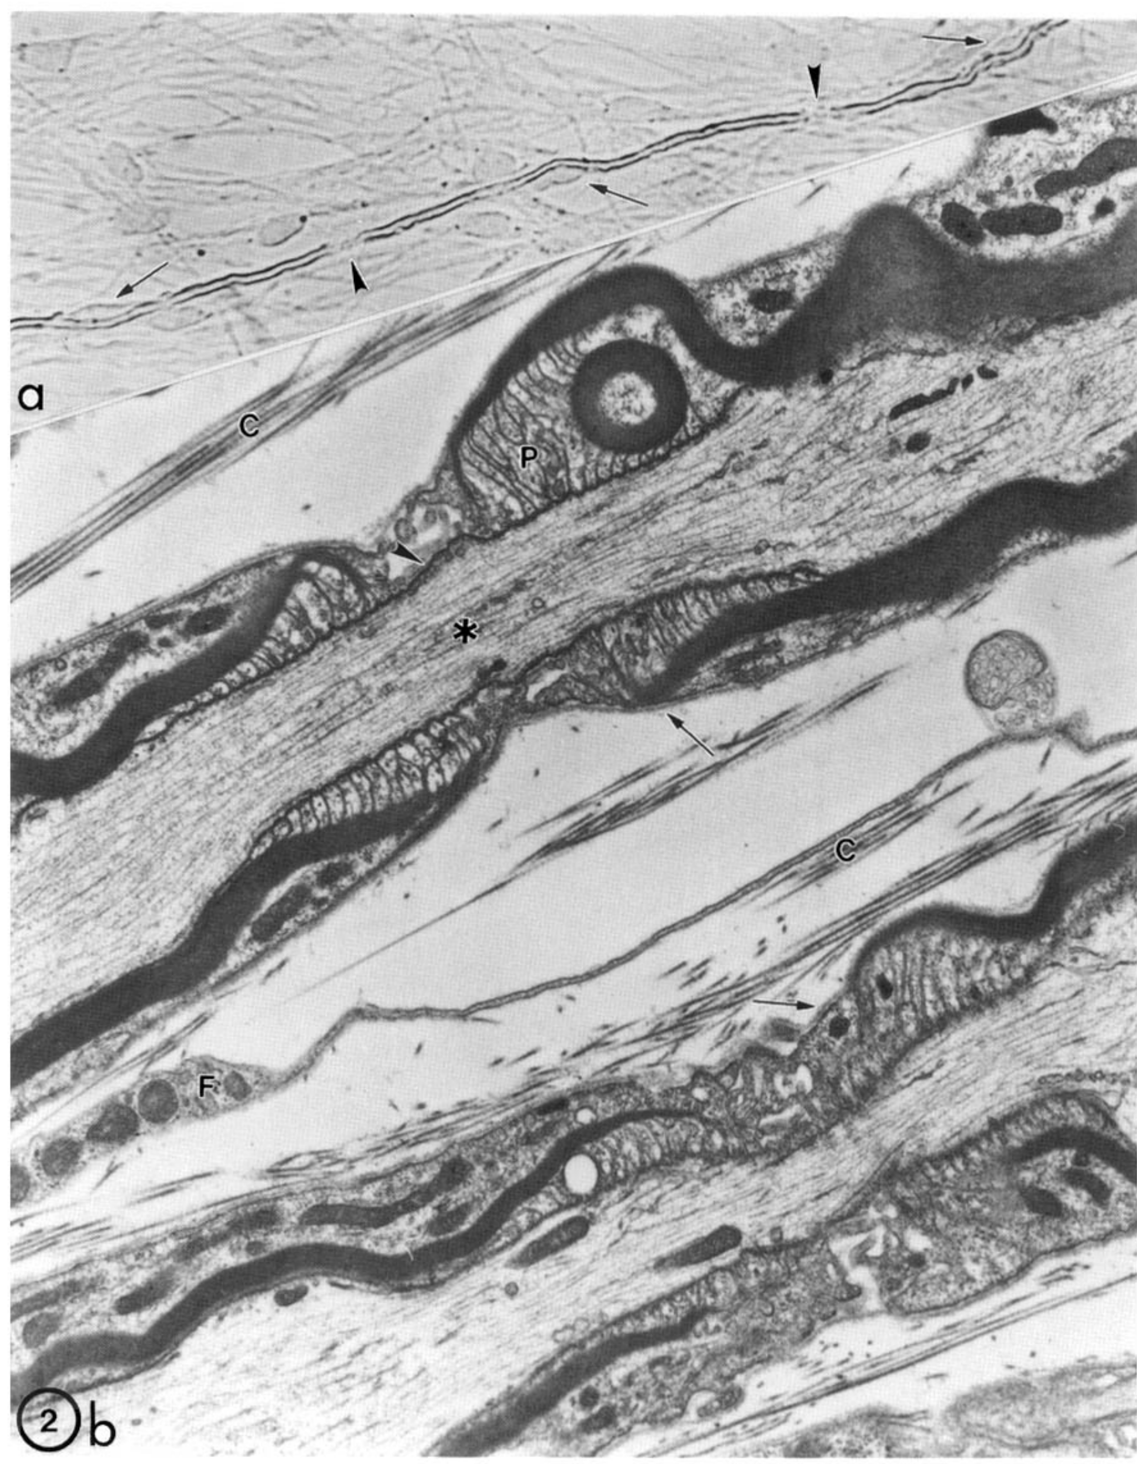

FIG. 3-2. (A) Myelin segments. One myelinated axon from a dorsal root ganglion neuron/Schwann cell coculture is shown. Three Schwann cells (*arrows* point to their nuclei) have positioned themselves along the axon and have elaborated three segments (internodes) of myelin. The nodes of Ranvier are seen as gaps between adjacent myelin segments (*arrowheads*). ×1000. (B) Nodes of Ranvier. By electron microscopy the node of Ranvier is characterized by a constriction of the axon and compaction of cytoskeletal elements (*). The axolemma (*arrowhead*) appears denser and thicker at the node. The myelin membranes seen as paranodal loops (*P*) are less compact, and more cytoplasm is found here than between adjacent myelin lamellae. Schwann cell processes lie over the axon at the node of Ranvier. Basal lamina (*arrows*) is continuous along the entire Schwann cell surface and traverses the nodal region. Longitudinally arranged collagen fibrils (*C*) are present in the extracellular space and a fibroblast (*F*) is seen between the two myelinated axons. ×20,000. [Courtesy of Dr. Eiko Okada.]

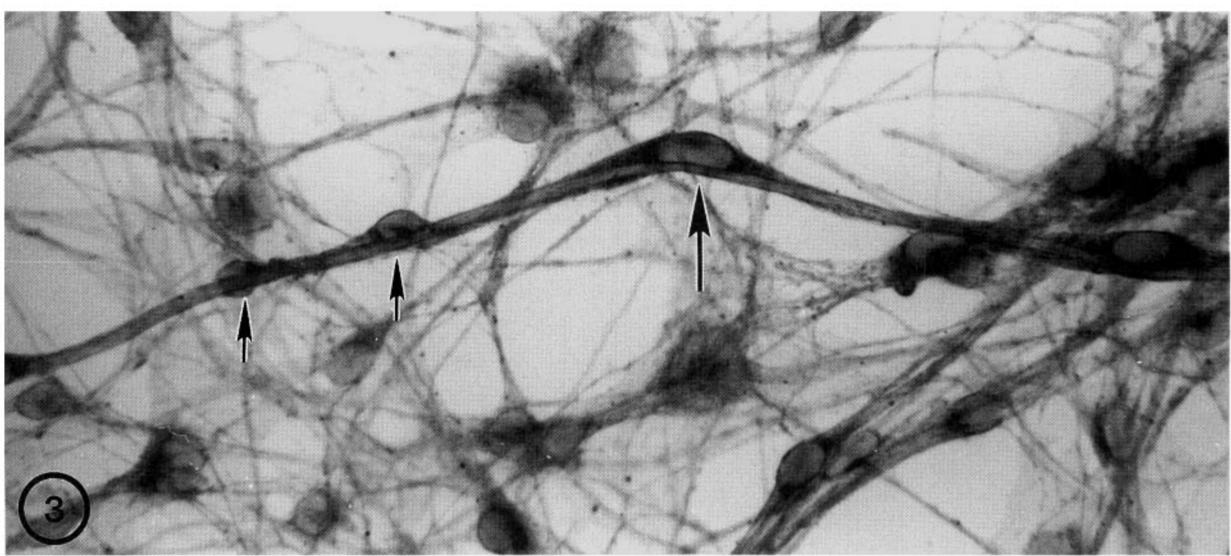

FIG. 3-3. Schwann cells beginning the process of myelination along an axon approximately 1 μm in diameter (which traverses the width of the field) compete for axolemmal space. The Schwann cell (*large arrow*) is laying claim to a substantial length of the axon preparatory to initiating the deposition of myelin, and in the process is pushing aside two adjacent Schwann cells (*small arrows*). It is not clear whether these redundant Schwann cells survive and find alternate function, or die. From a culture containing sensory neurons to which a purified population of Schwann cells was added. ×500.

and is interspersed with substantial regions of retained cytoplasm (Thomas et al., 1993).

The end result of the process of myelination in the peripheral nervous system is the deposition of a segment of spiraled compacted membrane, which occupies an axon length between 250 and 1000 μm and is separated from the adjacent segment by a node of Ranvier (Figures 3-1B and 3-2). With the deposition of these segments, the underlying axolemma is modified so that certain of the sodium channels that characterize excitable tissues are concentrated in the region exposed to the external environment at the node of Ranvier (Chiu, 1993). It is the concentration of these ion channels at the nodes that provides for focal current generation and leads to saltatory conduction. Details of the physiology of the myelinated axon and the specific function of the components of the node of Ranvier are discussed in Chapter 40. The manner in which the structure of the axon enclosed within myelinating Schwann cells is modified by this ensheathement is discussed in detail in Chapter 51.

The Ultrastructure of Schwann Cells

After reaching maturity, Schwann cells typically have a small ovoid nucleus containing a substantial amount of condensed chromatin, often clumped both at the nuclear periphery and near the center of the nucleus where one or more nucleoli are typically seen. Schwann cell cytoplasm is dense, containing both free and membrane-associated ribosomes, many rounded mitochondria, the Golgi apparatus, and a centromere found in the perinuclear region. The cytoplasm also contains lysosomes, vesicular bodies, and peroxisomes approximately 0.2 μm in diameter. Schwann cells contain microtubules of standard dimension and intermediate filaments. These and other cytoskeletal elements of the Schwann cell are considered in detail in Chapter 42. The nuclear and cytoplasmic characteristics of myelinating and nonmyelinating Schwann cells are similar (Figure 3-1A, B).

SCHWANN CELL INTERACTIONS WITH AXONS AND FIBROBLASTS

The expression of the higher differentiated functions of the Schwann cell is regulated by contact with the axon and, in some instances, enhanced by interactions with fibroblasts. Four aspects of Schwann cell function are known to be directly controlled by axonal contact: differentiation into an ensheathing or myelinating cell, myelin segment length, proliferation, and basal lamina production.

Axons Determine Whether a Schwann Cell Will Ensheathe or Myelinate

It has long been recognized that axonal properties determine whether Schwann cells will myelinate or

ensheathe axons. This was definitively shown by cross-anastomosing myelinated with nonmyelinated nerves and observing that the resident ensheathing Schwann cells of nonmyelinated nerve stumps differentiated into myelinating Schwann cells when interacting with axons originating from myelinated nerves (Weinberg and Spencer, 1975; Aguayo et al., 1976a, 1976b). Loss of axonal contact causes myelinating Schwann cells to stop expressing or to reduce the level of expression of myelin-associated glycoprotein, protein zero, myelin basic protein, and peripheral myelin protein 22, and to express glial fibrillary acidic protein, neural cell adhesion molecule, and nerve growth factor receptor (Politis et al., 1982; Poduslo, 1984; Jessen et al., 1987a; Tanuichi et al., 1988; Trapp et al., 1988; Mitchell et al., 1990; Fan and Gelman, 1992; Snipes et al., 1992). The expression of the sulfatide O4 and galactocerebroside are also downregulated upon loss of axonal contact in both myelinating and ensheathing Schwann cells, whereas S-100 expression remains constant in both Schwann cell types (Jessen et al., 1985; Jessen et al., 1987b). Thus, signals from axons are important determinants of phenotypic-specific gene expression in Schwann cells; these signals, however, have not been identified. Voyvodic (1989) has shown that increasing the target size of sympathetic axons, which are normally unmyelinated, will cause axon diameter to increase; these enlarged axons then become myelinated.

Axon Diameter Determines the Length of the Myelin Segment

Axons and Schwann cells also interact to influence axonal diameter; this, in turn, influences myelin internode length. The evidence that maturation of axons to full diameter depends on the presence of normal Schwann cells and the formation of myelin sheaths has been recently reviewed (Aguayo and Bray, 1984; Hoffman and Griffin, 1993). Axonal diameter is decreased in cases in which myelin sheaths are lost, as in the naked axons of the spinal roots of the mutant dystrophic mouse (Aguayo et al., 1979). Remyelination increases axon diameters of demyelinated axons and ensheathement increases axon diameter in dystrophic mice. Transplants of normal Schwann cells have the capability of increasing the abnormally small diameter of axons in the mouse mutant *trembler* (de Waegh et al., 1992). Tissue culture experiments have provided direct demonstration that axon diameters are increased in areas of cultures which contain Schwann cell ensheathement as compared to adjacent regions in the same culture where the axons are not ensheathed (Windebank et al., 1985).

Axons Are Mitogenic for Schwann Cells

The influence of axon contact on Schwann cell numbers has been established *in vitro* and *in vivo* (for review, see DeVries, 1993). The number of Schwann cells produced during embryogenesis can be decreased by decreasing the number of nerve fibers within peripheral nerve trunks (Aguayo et al., 1976c). In tissue culture, it is possible to directly demonstrate that axon contact influences Schwann cell proliferation and, moreover, that direct contact between the axon and Schwann cell is required (Wood and Bunge, 1975). This *in vitro* work has established that the mitogenic agent is a component of the axon surface (Salzer and Bunge, 1980). Evidence has recently been provided that the mitogenic activity expressed on rat cultured sensory neurons is associated with a heparin sulfate proteoglycan component of the neurites (Ratner et al., 1985). Axolemmal preparations derived from adult central white matter and adult sciatic nerve are also mitogenic for Schwann cells (DeVries et al., 1982; Sobue et al., 1983). DeVries has recently compared the neuritic and axolemmal mitogens and has presented evidence suggesting that these are different molecules, per-

FIG. 3-4. Evidence that the circumnavigation of the axon by the Schwann cell during myelination reflects advance of the inner rather than the outer end of the membrane spiral. *a–g* document the nuclear (*small arrows*) movement that occurred during a 44-hour observation period; the positions at 6 (*a, east*), 15 (*b, west*), 18 (*c, below the axon*), 20 (*d, east*), 28 (*e, west*), and 44 (*f, west*) hour of observation are shown. *a–e* illustrate $1^1/_2$ rotations (*east-west-east-west*) and *f* shows the results of a further rotation (*west-east-west*). Myelin formed during the observation period; the distinctive refractivity of myelin is apparent in *e* and *f*. In all, the nucleus circumnavigated the axon $2^1/_2$ times, illustrating that the nucleus can move substantially in early myelination and systematically in one direction. The direction in which the inner Schwann cell lip is pointed (counterclockwise; *h, arrow*) corresponds to the direction of nuclear circumnavigation. *i* shows a level of the internode ≈100 μm away from that illustrated in *h*. (*a–f*) Living culture. Bars: (*a–f*) 10 μm; (*h, i*) 0.5 μm. The inset (*J*) summarizes the concept. It shows a transversely sectioned, myelinating Schwann cell in the early phases of mesaxon formation preceding myelination. Circumnavigation of the axon by the Schwann cell nucleus is observed during early myelinogenesis to be in the direction of the inner lip of the spiraling Schwann cell process and opposite the direction of the outer lip. [From Bunge et al. (1989), with permission of The Rockefeller University Press.]

haps changing with the maturation state of the axon. He has also summarized the data available on the intracellular and molecular events which occur subsequent to mitogenic stimulation (DeVries, 1993).

Several methods are now available which allow separation of Schwann cell populations from both developing and adult peripheral nerve (Brockes et al., 1979; Morrissey et al., 1991). This has allowed a general analysis of the agents capable of inducing proliferation of Schwann cells that are not in contact with axons. Brockes and coworkers (Brockes et al., 1980; Lemke and Brockes, 1984) first identified a potent mitogen from bovine pituitary gland, a peptide termed *glial growth factor,* which now has been cloned and sequenced (Marchionni et al., 1993). There are three forms of the growth factor, which are products of alternative splicing of a single mRNA. The gene that encodes human glial growth factor also encodes several ligands known as *heregulins* for the $p185^{erbB2}$ receptor tyrosine kinase, which is structurally related to the epidermal growth factor receptor (Holmes et al., 1992). The homologous genes in chicken and rat encode the acetylcholine receptor inducing activity and *neu* differentiation factor, respectively. These three related factors may play key roles in the development and regeneration of the nervous system (Wen et al., 1992; Falls et al., 1993; Lemke, 1993; Reynolds and Woolf, 1993).

It is now known from the work of Davis and Stroobant (1990) (among others) that additional growth factors for Schwann cells include transforming growth factors β1 and β2. Acidic and basic fibroblast growth factor, and several forms of platelet derived growth factor are effective mitogens when used in combination with agents that raise intracellular cyclic amp levels. DeVries (1993) has recently reviewed other agents that influence the Schwann cell's responsiveness to mitogens. These molecules include proteases, extracellular matrix components, and products of myelin degradation.

Axons Induce Schwann Cells to Form Basal Lamina

An extensive series of studies over the past decade has established that axonal contact directly influences the deposition of basal lamina by the Schwann cell. This work has also demonstrated that basal lamina production is essential for Schwann cell function (for review see M. Bunge, 1993; M. Bunge et al., 1989b). As has been discussed above, this basal lamina deposition is characteristic of each axon-Schwann cell unit formed during the development of peripheral nerve. The contributions of axon-Schwann cell contact and of Schwann cell-fibroblast interaction in the deposition of the basal lamina and other connective tissue components of the peripheral nerve have been studied in a series of tissue culture experiments in which these three cell types have been grown in various combinations. When grown in isolation, Schwann cells express both laminin and proteoglycan on their surface, but do not organize a basal lamina (Carey et al., 1983; Cornbrooks et al., 1983; Eldridge et al., 1989). If Schwann cells are cocultured with neurons in a fibroblast-free system, it can be demonstrated that basal lamina is formed around each axon-Schwann cell unit, and a small number of collagenous fibrils are deposited (M. Bunge et al., 1980; M. Bunge et al., 1982; Eldridge et al., 1987). This demonstrates that the Schwann cell is able to generate basal lamina components when in contact with axons without the aid of fibroblasts. If neurons are removed from a culture of Schwann cells and neurons after a substantial basal lamina has been deposited, the basal lamina is retained. If this basal lamina is removed by enzymatic digestion, the orphan Schwann cell will not form a new basal lamina unless contact with axons is restored (M. Bunge et al., 1982).

Fibroblasts Enhance Schwann Cell Function

Recent experiments have shown, however, that the fibroblast is very much involved in cooperating with the Schwann cell in depositing basal lamina around the axon-Schwann cell units that characterize nonmyelinated nerve fibers (Obremski et al., 1993a). In cultures of sympathetic neurons whose axons are not normally myelinated, ensheathement of the axon is incomplete unless fibroblasts are present. In the presence of fibroblasts ensheathement is brought to completion and a full basal lamina is deposited around each axon-Schwann cell unit. It has further been demonstrated that this fibroblast influence on Schwann cell behavior can be mediated by materials released from fibroblasts, and does not require immediate contact between these two cells (Obremski et al., 1993b). Biochemical analyses of these types of preparation have shown that Schwann cells are capable of secreting types I, III, IV, and V collagen, as well as laminin and proteoglycans (Carey et al., 1983; Eldridge et al., 1989). Type IV collagen and laminin, the major components of basal lamina, are prominent products of Schwann cells studied in culture when in contact with axons (M. Bunge, 1993).

SCHWANN CELL FUNCTION IN INJURY AND REPAIR

Schwann Cell Reactions in Wallerian Degeneration

The remarkable versatility of the Schwann cell is well illustrated in the responses that it undergoes during the process of axonal breakdown known as Wallerian degeneration (for review see Griffin et al., 1993). When a peripheral nerve is transected there is a prompt breakdown of the amputated axon distal to the cut over a period of 12 to 24 hours. Concomitant with this the myelin sheath also begins to break down. As the myelin and axon disintegrate, both the resident Schwann cells (Figure 3-5) as well as hematogenous macrophages (which are recruited into the nerve by the degenerative process) are involved in the removal of axonal and myelin debris (Stoll et al., 1989). Shortly after the beginning of this breakdown, many of the Schwann cells in a nerve undergoing Wallerian degeneration enter the cell cycle. The Schwann cell division begins 3 to 4 days after a nerve is cut and continues for the subsequent 3 weeks after injury. Griffin and his colleagues (1990) have presented evidence that during this period of cell proliferation there is a release of diffusible factors, which influence not only the Schwann cells involved in the process of myelin breakdown but also nearby nonmyelinating Schwann cells, endoneurial fibroblasts, and perineurial cells. Within several days after nerve injury, the Schwann cells distal to the injury change their synthetic program, with a marked reduction in synthesis in myelin constituents. Thus, the Schwann cells lose a number of their phenotypic markers that are associated with myelin maintenance, including the expression of protein zero, galactocerebroside, and myelin basic protein.

Concomitant with this loss of phenotypic markers, Schwann cells begin synthesis of a number of trophic factors, including nerve growth factor (Heumann et al., 1987), brain-derived neurotrophic factor (Acheson et al., 1991), neurotrophin 3 (Schechterson and Bothwell, 1992), and platelet-derived

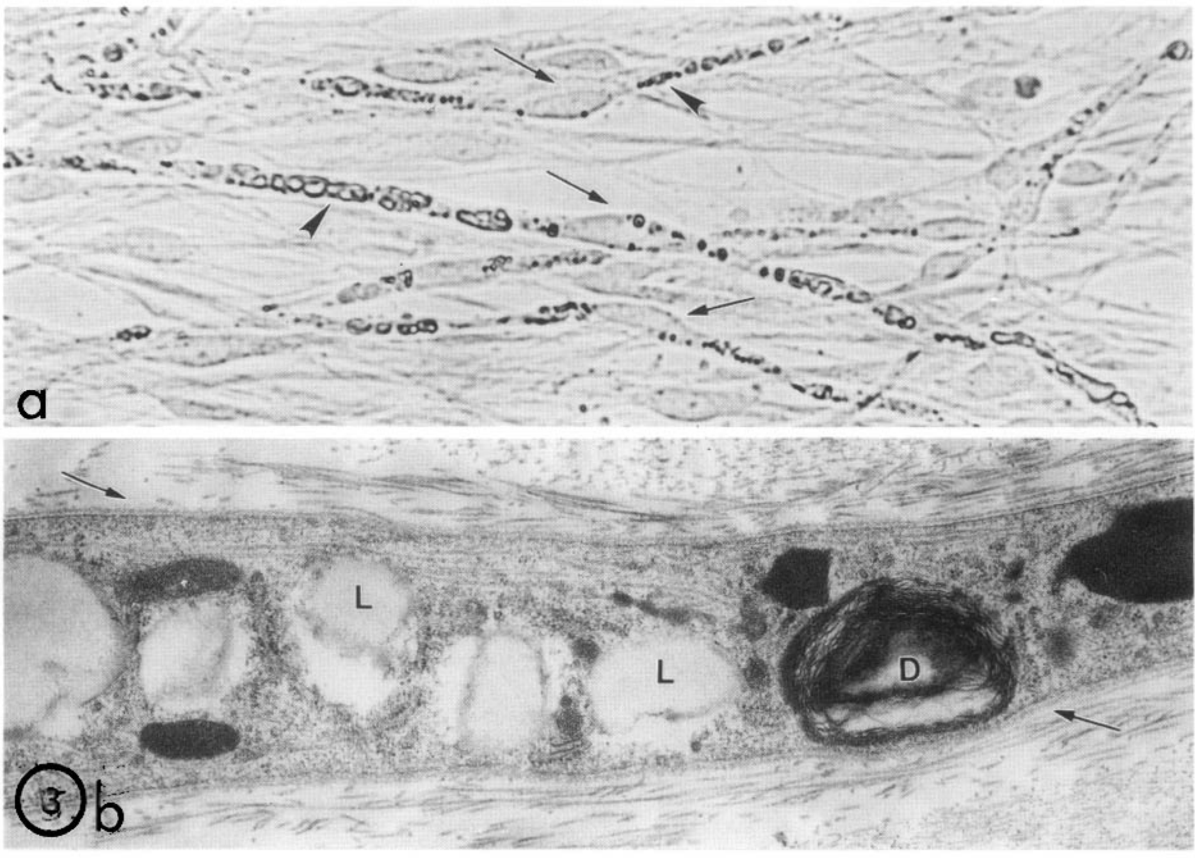

FIG. 3-5. (**A**) Myelinating axons undergoing Wallerian degeneration. Several myelin-forming Schwann cells (*arrows* point to location of their nuclei) in a dorsal root ganglion neuron-Schwann cell coculture 3 days after severing axons show fragmentation of their myelin sheaths (*arrowheads*). Schwann cells remain elongated within the basal lamina tube (see below) although the axon has degenerated. ×1000. (**B**) A Schwann cell 6 days after initiation of wallerian degeneration. The cytoplasm is filled with myelin breakdown products, including lipid droplets (*L*) and membranous fragments of myelin debris (*D*). The Schwann cell is elongated and basal lamina (*arrows*) is retained along its surface. ×25,000.

growth factor (Eccleston et al., 1990). These factors are downregulated with Schwann cell differentiation and upregulated in Wallerian degeneration. An exception is the trophic factor ciliary neurotrophic factor, which is upregulated in Schwann cells during full differentiation (Rende et al., 1992). The levels of ciliary neurotrophic factor in Schwann cells are decreased during Wallerian degeneration (Friedman et al., 1992).

Role of Schwann Cells in Regeneration

The responses of the Schwann cells in the process of Wallerian degeneration described in the preceding section are an important prelude to the Schwann cell's role in regeneration (for review see R. Bunge and Hopkins, 1991). Because the connective tissue components of the peripheral nerve (including the tubular basal lamina present around each axon-Schwann cell unit) are preserved within the nerve trunk distal to an injury, those Schwann cells that have been involved in the phagocytosis and digestion of myelin retain residence within endoneurial tubes and are in a position to await the arrival and then to assist the regrowth of axons. There has been an ongoing debate regarding the importance of the Schwann cell vis-à-vis the extracellular matrix components of the peripheral nerve, in fostering the process of regeneration in the peripheral nervous system (for reviews see Kromer and Cornbrooks, 1987; M. Bunge et al., 1989b; for discussion see Kleitman et al., 1988; Paino and Bunge, 1991). It now seems clear that, whereas the components of the extracellular matrix, which form the basal lamina retained in the distal nerve stump in Wallerian degeneration, are able to promote some degree of axonal regrowth, this regrowth is much more effective if these basal lamina tubes are occupied by Schwann cells (Ide et al., 1983; Ard et al., 1987; Bixby et al., 1988; Kleitman et al., 1988; Hopkins and Bunge, 1991). When axons are allowed to grow into peripheral nerves in which the Schwann cells have been removed, the process of regrowth is less vigorous and, as the axons grow, they are accompanied by Schwann cells migrating in from the proximal stump of the cut nerve (Sketelj et al., 1989). In the peripheral nerve of the rodent the process is rapid, and remyelination of the regrowing axons in the distal stump occurs within 3 weeks after injury. It should be noted that Schwann cells resident within peripheral nerves subjected to myelin loss (demyelination) are capable of promptly replacing the lost myelin segments (Griffin et al., 1990). Because there is no subsequent growth of the remyelinated nerve, these segments will generally remain shorter than those which have been retained from the neonatal period, thus allowing recognition of the remyelinated nerve fiber. Schwann cells isolated from adult peripheral nerve and expanded in tissue culture have been demonstrated to be effective in promoting peripheral nerve regeneration when aligned within a guidance channel and placed between cut ends of the sciatic nerve of the rat (Guenard et al., 1992).

CONCLUDING REMARKS

It has now been shown in a number of situations that purified populations of Schwann cells taken from the peripheral nervous system have the capability of engendering considerable axonal regeneration within the central nervous system (Kromer and Cornbrooks, 1985; Paino and Bunge, 1991; Xu et al., 1994). Because we can now separate the Schwann cell population from the other cellular and matrix components of the adult peripheral nervous system (Morrissey et al., 1991; Rutkowski et al., 1992), it is possible to isolate Schwann cell populations, to expand their numbers, and to use them to construct cellular protheses to influence the regeneration of both central and peripheral neural tissues (Guenard et al., 1992; Levi et al., 1994; Xu et al., 1994).

We are grateful to Mary Bunge for help with the figures and to Charlaine Rowlette for manuscript preparation. Work in the author's laboratory is supported by grants NS09923-23, NS19923-10 from the National Institutes of Health, and by The Miami Project to Cure Paralysis.

4 Ependymoglia and ependymoglia-like cells

ANDREAS REICHENBACH AND STEPHEN R. ROBINSON

DEFINITION, OCCURRENCE, AND PHYLOGENY OF EPENDYMOGLIA

This chapter argues for the view that vertebrate radial glia, ependymal cells, and supporting cells of sensory epithelia share a common evolutionary origin, and that they are functionally and structurally homologous. The Greek term *ependyma* (επι=upon; ενδυμα=garment) was introduced to designate the cell layer that lines the ventricular spaces of the vertebrate brain. Thus, ependymoglial cells are defined here as glial cells that extend one of their processes (or abut with their soma) to the lumen of the ventricular system, and contribute to the apical surface of neural tissue (tissue that is epithelial in deuterostomes, to which vertebrates belong) (see Table 4-1). Typically such cells are bipolar, and their processes may span the entire width of the neural epithelium (*radial glia*). Some types of ependymoglia (e.g., fetal radial glia, Müller cells) have been classified as "astrocytes" by some authors, but, as will be seen in this chapter, they possess many features not shared by astrocytes. Conversely, astrocytes with radially aligned processes (e.g., Bergmann glia) have sometimes been included with ependymoglia. These cells, however, do not establish contact with the apical surface of neural tissue, and they lack many of the features that characterize ependymoglia.

Ependymoglia-like cells are found in the central nervous system of invertebrates that have epithelial nervous systems (i.e., deuterostomes—with the exception of chaetognatha, some turbellarians, and some oligochaetes) and in the sensory epithelia of most animal phyla. These cells abut a fluid- or mucus-filled lumen, and have a bipolar morphology. Such cells do not occur in nonepithelial nervous tissues, where both an apical surface and a fluid-filled lumen are missing. They are absent from the peripheral ganglia of vertebrates (which arise from migrating neural crest cells) and from the ganglionic central nervous system of most protostomes where the epithelial character of the tissue is lost in early development.

Since ependymoglia-like cells in invertebrates provide insights into the possible phylogenetic origins of ependymoglia, we begin with a brief discussion of these cells, followed by a review of ependymoglia-like cells in placode-derived sensory epithelia, and, finally, we discuss "classical" ependymoglia. The last part of the chapter deals with general types and possible growth mechanisms of ependymoglial cell processes, the ontogeny of ependymoglial cells, and the relationship of ependymoglial cells to astrocytes. Several excellent reviews of ependymoglia have already been published (e.g., Leonhardt, 1980; Bruni et al., 1985).

Phylogenetic Origin of Ependymoglia-like Cells

In coelenterates, neuronal cells are scattered throughout the epidermal tissue, but in some medusae rather elaborated sensory epithelia (Pearse and Pearse, 1978) and ganglia (Horridge and McKay, 1962) occur. Even the most primitive deuterostomes have an epithelial central nervous system that is linked to epithelial sensory fields (cf. Bullock and Horridge, 1976) (see Figure 4-1). In these animals (e.g., starfish) the cell-dense apical zone of the nervous system forms part of the body wall and is separated by a thin cuticle from the seawater. Sensory neurons in this zone direct their receptive processes into this environment, and deliver signals to multipolar ganglion cells that distribute this information laterally via a nerve fiber layer of considerable thickness, which forms the inner zone of the nervous tissue. "Epidermal" or "supporting" cells compose a third cellular element of this system, and have long, radial processes that span the entire thickness of the tissue up to the basal lamina beneath the underlying mesenchyma (Meyer, 1906; Bargmann et al., 1962; Rehkämper et al., 1987). These cells closely resemble vertebrate ependymoglia (see also Figure 4-3A).

There are good arguments to support the view that ancestral chordates were derived from larval forms of primitive deuterostomes (i.e., are of neo-

TABLE 4-1. *Types of Ependymoglia and Related Cells Found in Vertebrates*

Cell Type	Tissue
Ependymoglia (radial glia)	
Tanycytes	Brain and spinal cord
Tanycyte-like (e.g., coronet) cells	Circumventricular organs
Support cells	Parietal/pineal organ
Müller cells	Retina (lateral eye)
Ependymocytes	
Ciliated ependymocytes	Lining of ventricles
Choroid plexus epithelial cells	Circumventricular organs
Lens cells	Parietal eye
Pigment epithelial cells	Lateral eye
Ependymoglia-like cells	
Supportive cells	Ampullary electroreceptor
Support cells	Neuromast organ
Support cells	Vestibular organ
Support (pillar, border, Deiters', Hensen's and Claudius') cells	Organ of Corti
Supporting (sustenacular) cells	Olfactory epithelium
Supporting (light) cells (?)	Taste bud

tenic origin: e.g., Garstang, 1928; Bone, 1981; Lacalli, 1990; Crowther and Whittaker, 1992). The nerves of such larvae (as in the related lophophorates: Figure 4-2B) are mostly intraepithelial, and are ensheathed by ependymoglia-like cells. The ciliary bands of these larvae (Figure 4-2A) are thought to have been the precursors of the vertebrate neural plate and tube (e.g., Lacalli et al., 1990); their nervous system consists of the same principal types of cellular elements as that of the adult animals. Thus, the "prototype" neural tube was probably an "enfolded" or "enrolled" version of the epithelial nervous tissue shown in Figure 4-1, and was composed of sensory cells (cerebrospinal fluid contact neurons: Vigh et al., 1969), multipolar ganglion cells, and ependymoglia-like cells. Even in the earliest vertebrates, this kind of central nervous system seems to have been interconnected with ectodermal sensory epithelia, consisting of receptor neurons and "supporting" cells (Northcutt and Gans, 1983).

TYPES OF EPENDYMOGLIA-LIKE CELLS

Figure 4-3 provides a survey on common ultrastructural features of ependymoglial and ependymoglia-like cell types in different nervous tissues of various animal species. All these cells have a bipolar shape and span the tissue between their apical pole that sends microvilli and/or cilia into a fluid-filled space, and their endfoot abutting the basal lamina. All these cells contain intermediate filaments that consist of specific proteins (cf. also Eng and Lee, Chapter 43, this volume). There are, however, other features specific for each particular radial glial cell; moreover, some ependymoglial cell types show different (non-radial) morphologies or extreme adaptations to special functional tasks.

Ependymoglia-Like Cells of Placodal Origin: Supporting/Sustentacular Cells of (Peripheral) Sensory Epithelia

In vertebrates, most sensory epithelia are derived from surface ectodermal placodes, and they can be specialized for mechanoperception (stato-acoustic systems with organs of Corti and vestibular organs; neuromast or lateral line organs in fish and amphibia), electroception (ampullary and tuberous receptor organs in fish and urodeles), or olfaction (nasal olfactory epithelium). Neurons in these sensory epithelia project their receptive organelles (generally a cilium) into a fluid- or mucous-filled lumen, and are enclosed by the processes of support cells. Since these support cells closely resemble ependymoglia, they will be briefly reviewed here, even though they are not true ependymoglia since they do not line the ventricular surfaces.

In electroceptive ampullary organs (e.g., Jørgensen et al., 1972) and most mechanoceptive epithelia (Lindeman, 1969), the apical poles of supporting cells fuse with those of adjacent cells to form an apical "membrane". Adjacent cells are generally joined by tight junctions. Most of these cells possess short microvilli that project into the lumen, and numerous mitochondria and glycogen granules are found near the bases of the microvilli, indicating that these are sites of intense metabolic exchange (Figures 3D, 4A). Such ependymoglia-like cells are generally columnar and span the entire thickness of the sensory structure. Their basal endfeet abut the underlying basal lamina, and surround the axons passing through the basal lamina.

The organ of Corti is unique among the mechanoreceptive epithelia because it contains so many distinct and specialized types of supporting cells, all of which are derived from columnar cells in the epithelium of the otic vesicle. Each type of cell extends from the basilar membrane to the free surface of the organ of Corti where their processes unite to form an apical (reticular) membrane. All of the spaces contacted by these cells are filled with endolymph. One type, the *pillar cell,* has a cement-like basal cone from which tonofilaments extend up to the apical

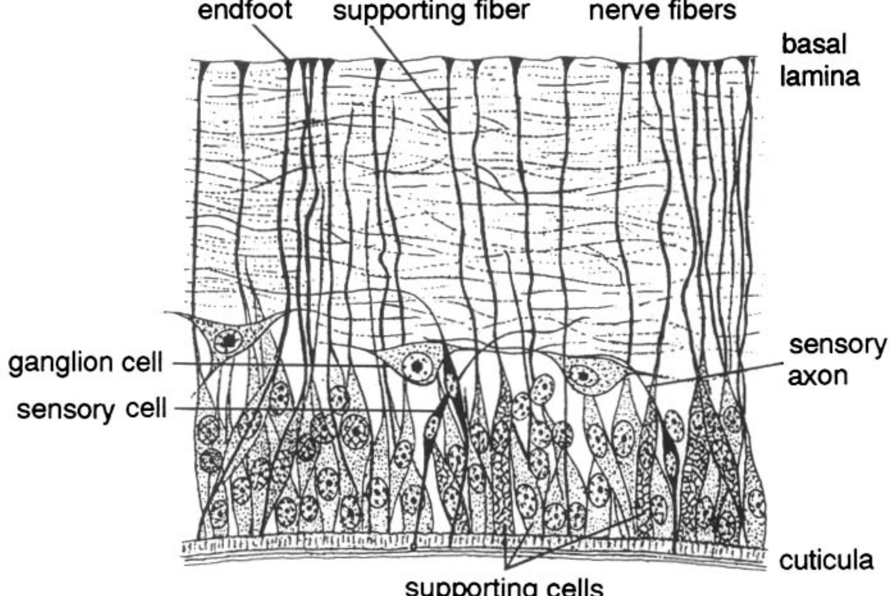

FIG. 4-1. Cross-section through the radial nerve of a starfish (*Asterias rubens*). Directly beneath the cuticula lies the so-called nuclear zone containing the somata of sensory cells, ganglion cells, and supporting cells, which later send long processes ("supporting fibers") through the entire thickness of the epithelium. The conical endfeet of these processes abut the basal lamina. [Redrawn after Figures 4 and 12 in Meyer (1906).]

end of the cell. Some of the tonofilaments are tubular (28 nm outer diameter), while others are microfilamentous (6 nm diameter), and together they form a regular, tightly packed array (Angelborg and Engström, 1972). A second cell type, *Deiters' cells* (outer phalangeal cells), have similar tonofilaments and support the outer hair cells. A third type, *border cells,* are located at the medial side of the organ. They enclose the inner hair cells. Laterally, *Hensen's cells* and *Claudius' cells* form a columnar epithelium that decreases in height with increasing laterality. Vimentin (considered as a marker of central nervous system ependymoglia) is present in two types of supporting cells in the mammalian organ of Corti: Deiters' cells and inner pillar cells (Oesterle et al., 1990).

Supporting ("sustentacular") cells in olfactory epithelia (Figures 4-3C and 4-16A) resemble those of mechanosensory epithelia, except that they contain pigment granules and secretory vesicles, and large Golgi complexes in the apical cytoplasm, indicating

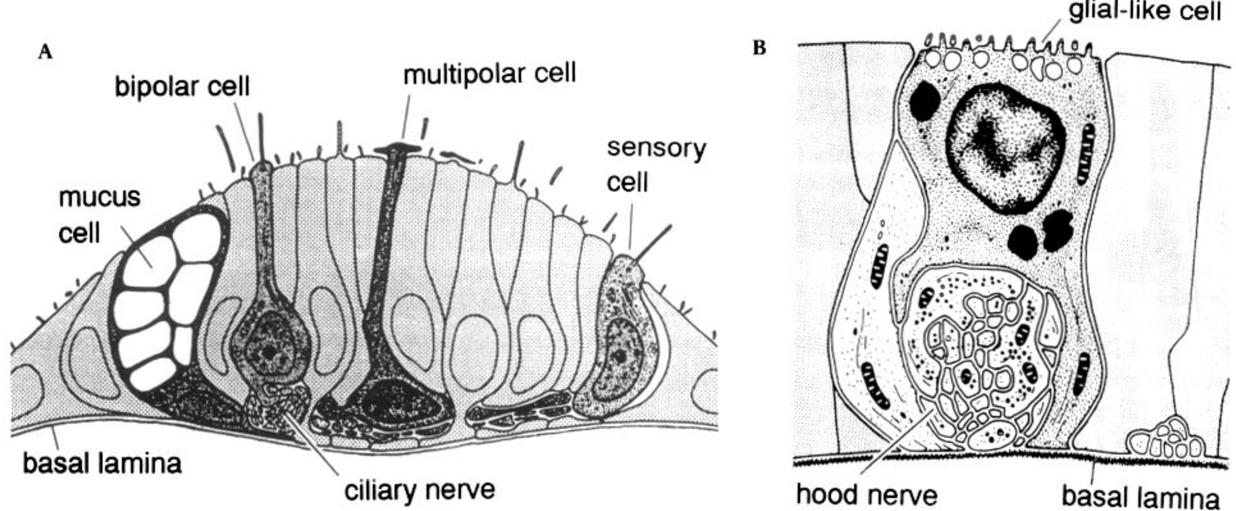

FIG. 4-2. "Supporting cells" of primitive larval nervous systems. **(A)** Transverse section through the ciliary band of the bipinnaria larva of a starfish (Deuterostomia). Three different types of neurons ("sensory," "bipolar," and "multipolar" cells; most probably, the ventricular processes of all three types have sensory functions) are embedded between ciliated supporting cells (*gray stippling*). **(B)** Epithelium of a lophophorate actinotroch larva (Protostomia, but closely related to ancestral stem forms leading to Deuterostomia). The primary hood nerve is ensheathed by a glial-like capsular cell that bears great similarity to supporting cells of vertebrates. [From Lacalli (1990), with permission.]

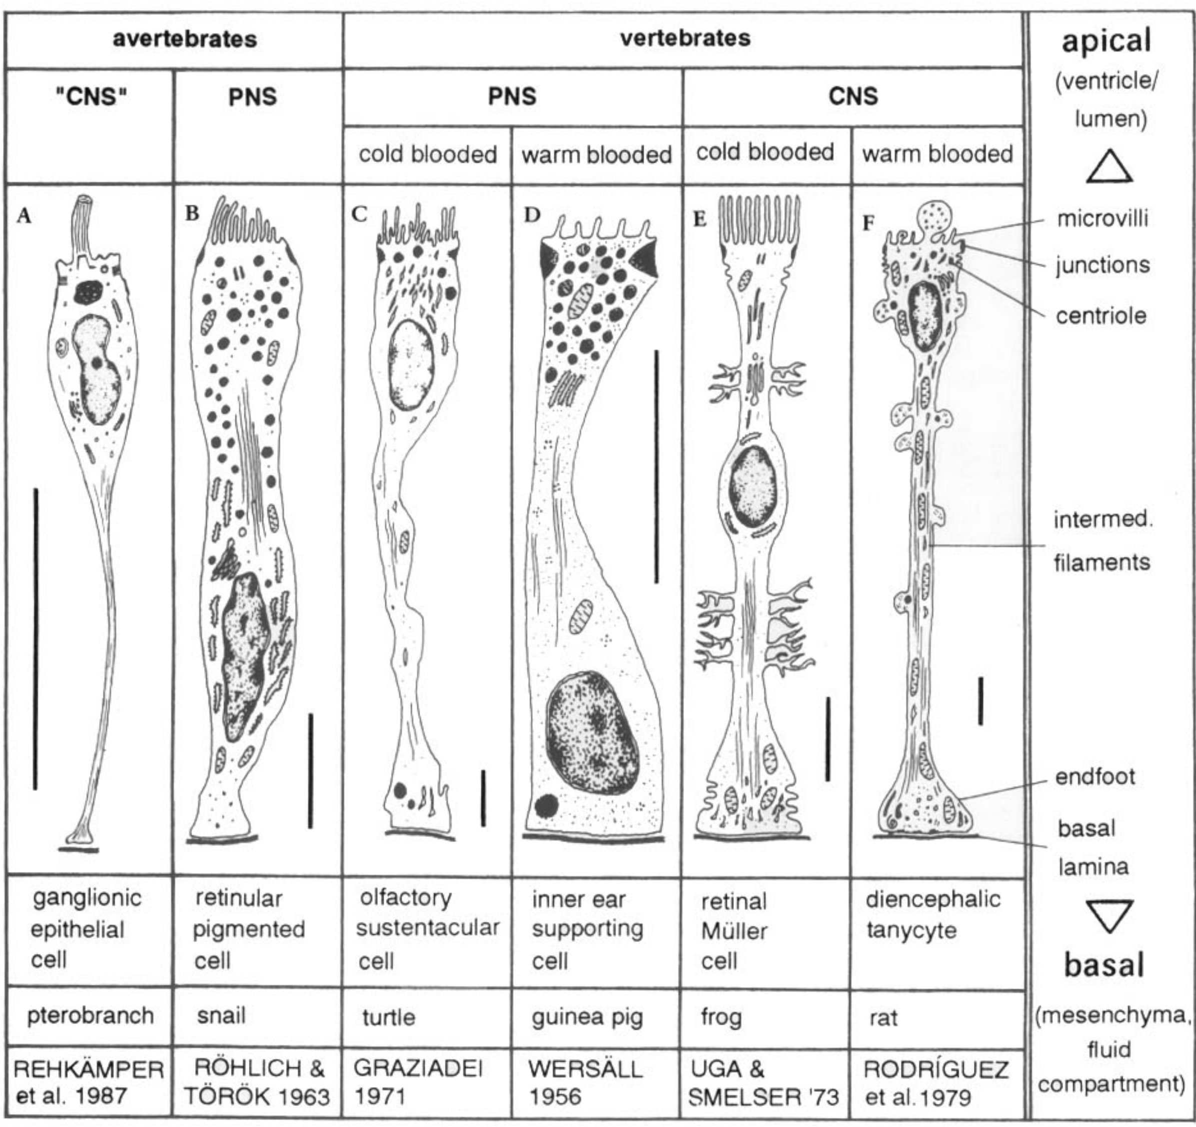

FIG. 4-3. Ultrastructure of various radial glial (or "supporting") cell types in peripheral (*PNS*) and central (*CNS*) nervous tissues of invertebrates and both cold- and warm-blooded vertebrates. The common features of these cell types are given at the right margin. The apical pole of all cells abuts a fluid- (or mucus-) filled space that might be the seawater environment in invertebrates, or the cerebrospinal fluid within the central canal in vertebrates. This pole is characterized by microvilli (and/or cilia), and by sophisticated apicolateral cell coupling. The opposite pole of the cells forms an endfoot at the basal lamina that demarcates the neuroepithelium from underlying mesenchyma. The processes of these cells may be rather long (bar = 20 μm), and contain particular filaments. (The cells were redrawn from the sources given at the bottom line.)

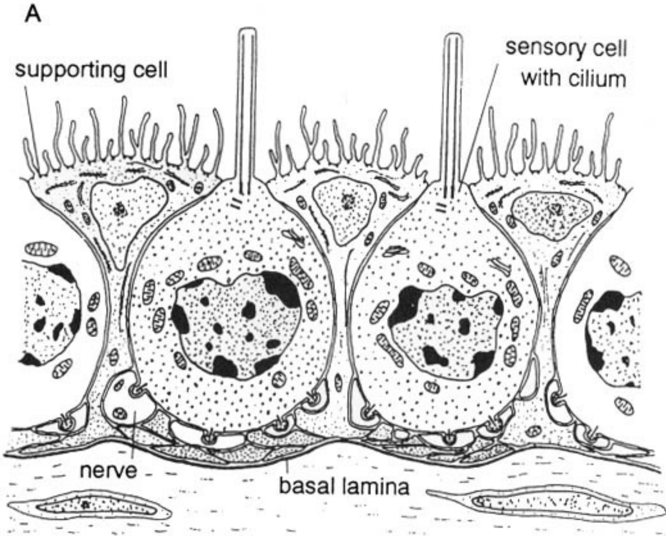
a secretory function. Secretions from their apical surface are thought to contribute to the mucous covering of the epithelium (Getchell et al., 1984), at least in lower vertebrates.

In contrast to the above-mentioned organs, which all arise from ectodermal placodes, gustatory organs (taste buds) develop from placodes within the endoderm. In heterothermic vertebrates, taste buds resemble neuromasts, and contain ependymoglia-like supporting cells (Figure 4-4C). In mammals, a type of supporting cell ("light cell") with ependymoglial features is also present, but the identity of these cells is uncertain. Some authors claim that light cells are actually immature taste receptor neurons, while others claim that they are a nonneuronal support cell and derive from a separate lineage (e.g., Farbman, 1980).

Similar sensory epithelia are found in invertebrate species. In most of these species, the eyes arise from



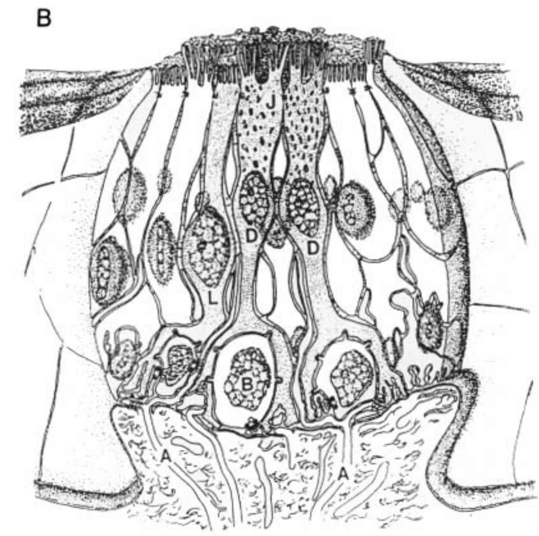


FIG. 4-4. Supporting cells. (A) Electrosensory epithelium in the Lorenzinian ampullary organ of a fish (*Polyodon spathula*). [From Jørgensen et al. (1972), with permission.] (B) A taste bud from *Necturus maculosus*. [From Roper (1989), with permission.] Type I, or dark cells (*D*) are receptor cells, whereas type II, or light cells (*L*) might be supporting cells. All cells are interconnected by apical junctional complexes (*J*). Basal cells (*B*) form synapses with other taste cells and with gustatory axons (*A*), suggesting that they may be a form in interneuron in the taste bud.

ectodermal anlagen outside the central nervous system. Supporting cells of such eyes mostly contain pigment granula (Figure 4-3B).

Ependymoglia of Neural Plate Origin: Central Nervous System Radial Glia and Ependymocytes

"Epithelial" Ependymocytes. In tunicate larvae, thought to be closely related to ancestral vertebrates, most of the neural tube consists of a simple arrangement of "epithelial" ependymocytes (Figure 4-5A). The lumen of their neural tube is enclosed by four (dorsal, ventral, and two lateral) rows of primitive ciliated ependymal cells (Crowther and Whittaker, 1992). There is basolateral contact to the two longitudinal axon bundles.

Within the central nervous system of vertebrates, there is at least one organ that consists of a homogeneous epithelium. The choroid plexus is found in all vertebrate taxa, including cyclostomes. The four choroid plexuses arise from invaginations of the single-layered roof plate; the early anlagen consist of glycogen-rich cells (cf. Dohrmann, 1970). The mature plexus appears as a convoluted vascular membrane whose surface is greatly increased by villi. In humans, the total surface area of the choroid plexuses has been estimated to be about 213 cm^2 (Voetmann, 1949). Each choroidal villus is composed of a single layer of cuboidal ependymocytes resting on a basal lamina, a layer of interposed connective tissue elements, and a blood vessel (mostly a thick capillary) beneath (Figure 4-5B).

The apical membrane of the ependymal cells typically extends large numbers of long microvilli, and a thin central bundle of kinocilia of the $9 \times 2 + 2$ type (the number of which varies with age and species) (Dohrmann, 1970). The lateral membranes are closely approximated, and tight junctions are established near the ventricular surface (Brightman and Reese, 1969). Numerous cristate mitochondria are dispersed throughout the cytoplasm and are often seen in close approximation to components of the abundant rough endoplasmic reticulum. The basal plasma membrane, which rests on the basal lamina, is elaborately infolded. Together with the apical microvilli, these basal infoldings characterize the choroid plexus as a transport epithelium. The choroid plexuses are responsible for most of the cerebrospinal fluid production by means of their apical sodium-potassium pumps that transport, into the lumen, an excess of sodium ions, which drag along water and soluble molecules (e.g., Wright et al., 1977). This function is subject to neuroendocrine regulatory mechanisms (cf. Nilsson et al., 1992).

There are obvious structural similarities between the ependymocytes of the choroid plexus and those of another epitheloid ependyma, the *retinal pigment epithelium* (Figure 4-5C). It separates a cavity, the subretinal space (a vestige of the embryonic optic ventricle), from the blood within the choriocapil-

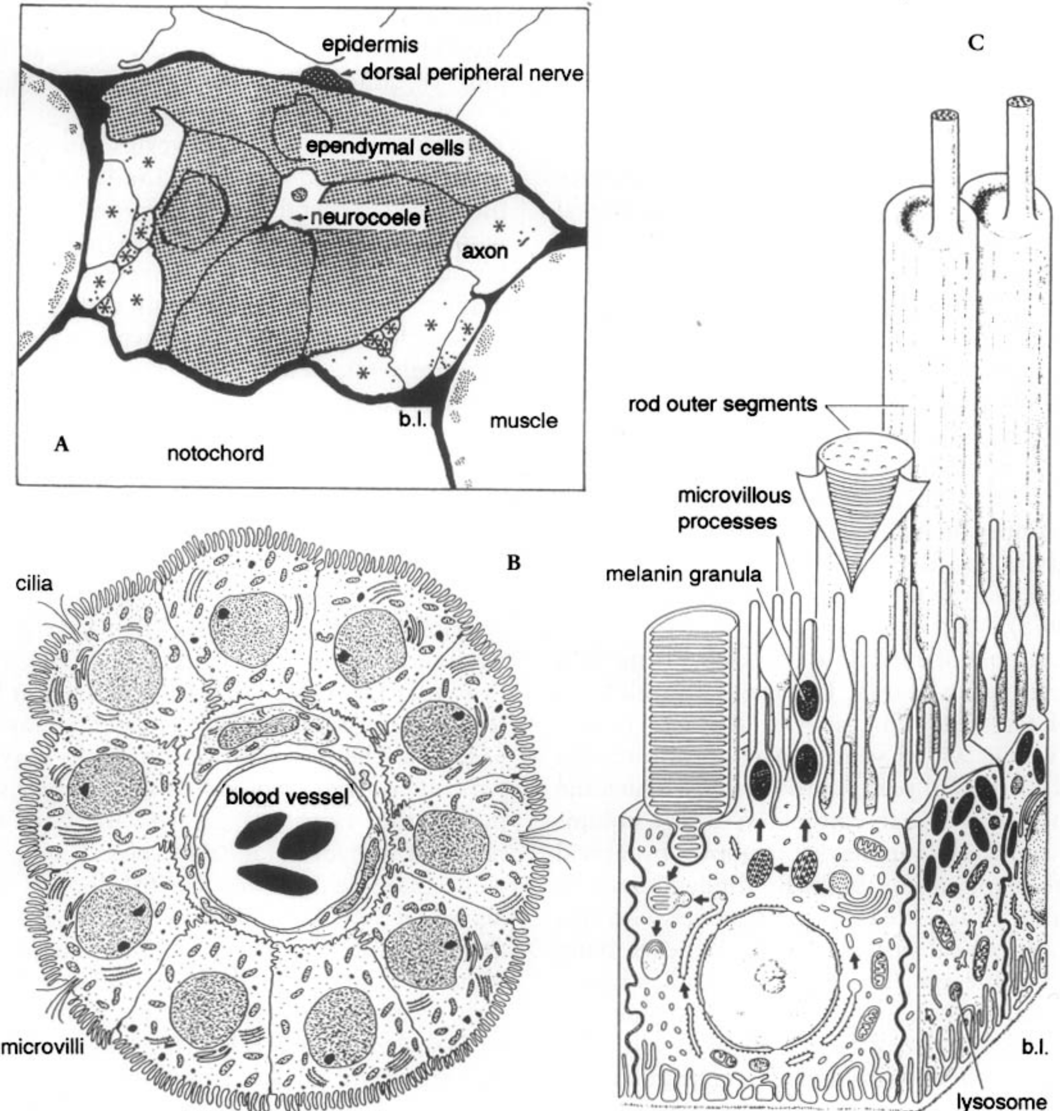

FIG. 4-5. "Epithelial" ependyma. (A) Transverse section through the central nervous system in the proximal tail region of a tunicate larva. The four ependymal cells are labeled by stippling, the seven axons at each side by asterisks. In the neurocoele, a cilium is visible [From Crowther and Whittaker (1992), with permission.] (B) Mammalian choroidal villus in cross section. The cuboidal epithelial cells have numerous microvilli on the apical membrane as well as tufts of cilia; lateral and basal membranes are infolded. A basal lamina (*not drawn*) lies beneath the epithelium. [From Dohrmann (1970), with permission. (C) Retinal pigment epithelium extending long (microvillous) processes between the outer segments of photoreceptor cells. [From Junqueira and Carneiro (1991), with permission.]

laris. Embryologically, the retinal pigment epithelium is formed from the medial wall of the optic vesicle, and its differentiation is probably induced by the neural retina. It functions as epithelium, macrophage, and glia (Steinberg, 1985).

The apical membranes of retinal pigment epithelium cells extrude profuse microvillous and sheath-like processes that are closely apposed to and ensheathe portions of the outer segments of rod and cone photoreceptor cells (Figure 4-5C, 4-12D). Apicolaterally, belts of tight junctions encircle the retinal pigment epithelium cells and contribute to the blood-retina barrier. The shed tips of photoreceptor outer segments (there is continuous renewal of outer segments by "disk shedding") are surrounded by pseudopodia from the apical retinal pigment epithelium surface and taken into the cytoplasm (Bok and Young, 1979). Such phagosomes are then fused with lysosomes and degraded. The cytoplasm is densely packed with rough endoplasmic reticulum and Golgi's complexes. These organelles are involved in melanin synthesis and the formation of the pigment granules ("melanosomes") that fill the apical cytoplasm and villous processes, and serve to absorb

stray light. Retinal pigment epithelium cells absorb fluid from subretinal space (and thus help to prevent retinal detachment), most probably by apical bicarbonate absorption (see Steinberg, 1985). The basal cytoplasm is rich in mitochondria to provide the energy necessary to drive this process, and the surface area of these cells is greatly increased by the apical microvilli and by elaborate infoldings of the basal plasma membrane.

The retinal pigment epithelium is continuous with similar epithelial ependymocytes. At the periphery, the retinal pigment epithelium undergoes a transition of into the pigmented outer layer of the ciliary epithelium. The latter extends up to the marginal fold where it is continuous with the inner nonpigmented layer of the ciliary epthelium. At the ora serrata, this nonpigmented ciliary epithelium changes over to cuboid ependymocytes that may be related to Müller cells of the adjacent neural retina (Pei and Smelser, 1968).

A final example of epitheloid ependyma is the lens of the parietal eye in lizards. This eye is derived from the roof of the embryonic neural tube as a noninvaginated vesicle whose ventral part constitutes the retina, and the dorsal part forms the lens. Thus, the parietal lens consists of an epithelium of high columnar ependymocytes that may contribute, by apical secretion, to maintenance of the fluid-filled lumen of the eye (Eakin et al., 1961). In congruence with this hypothesis, the apical surface of the cells bears many microvilli, and the apical part of the cytoplasm contains abundant mitochondria and vesicles (Eakin et al., 1961); the cytoplasm is rich in glycogen after dark adaptation. The basal (light-accepting) part of the cytoplasm contains a large fibrous mass with a dense spherical body at its center; the basal membrane abuts a basal lamina.

Central Nervous System Radial Glia I: Tanycytes. The term *tanycyte* (from the Greek *ταννειν* = to stretch) was introduced by Horstmann (1954) to describe (in sharks) ependymoglial cells whose processes extended over large distances. This term is now commonly applied to such ependymoglial cells of the adult brain and spinal cord (Figure 4-6). Tanycytes have been described in acrania, agnatha, selachian fish, teleostian fish, amphibians, reptilians, and birds (Stensaas and Stensaas, 1968a, 1968b; reviewed by Scharrer et al., 1980).

In adult mammals, tanycytes are restricted to the wall of the diencephalic third ventricle (Figure 4-7A, B, C), the dorsal and ventral walls of the mesencephalic aquaeduct (Figure 4-7D), the floor of the fourth ventricle, and the ventral part of the spinal central canal (Figure 4-7E). Tanycyte-like cells have also been reported in the lateral ventricles of adult rats (Hirano and Zimmerman, 1967) and in the velum medullare of adult primates (Reichenbach, 1990).

The various types of tanycytes can be classified in different ways. Horstmann (1954), for example, distinguished "ependymal tanycytes" (unipolar cells with their somata within the ependymal layer) from bipolar "extraependymal tanycytes" (with their somata elsewhere in the nervous tissue). Another discrimination can be made between (relatively short) "protoplasmic tanycytes" that have many side branches and protrusions within gray matter (e.g., Figure 4-7C, E), and (rather long) "fibrous tanycytes," whose processes are mainly smooth-surfaced, and extend through white matter (Figure 4-7A), although in many cases the cells have a shorter "protoplasmic" neck region and a longer "fibrous" tail process (Figures 4-7A, B). Finally, one may discriminate "pial tanycytes" that have processes extending to the pia mater (Figure 4-7A), from short "vascular tanycytes" that form endfeet at blood vessels in the proximity of the ependymal layer (Figures 4-7B, E). The processes of some cells may make *en-passant*-contacts to blood vessels on their way to farther distant targets (Figure 4-7B). With the exceptions of tanycytes in the ventral margin of the diencephalic third ventricle (Millhouse, 1971; Akmayev et al., 1973; Seress, 1980) and the velum medullare (Reichenbach, 1990), all mammalian tanycytes are of the vascular variety. These may be born rather late in ontogenesis (e.g., Altman and Bayer, 1978) whereas pial tanycytes may directly arise by differentiation from embryonic radial glia (see below).

Tanycytes have either one or no cilium, and various numbers of microvilli and larger protrusions from their apical surface (see Figure 4-3F). Together with endo- and/or exocytotic membrane vesicles, these specializations indicate an active exchange of substances with the cerebrospinal fluid. Neighboring tanycytes are interconnected via apicolateral junctions. In the hypothalamus as well as most circumventricular organs, adjacent tanycytes are interconnected by tight junctions that serve to separate the cerebrospinal fluid from the "blood milieu" surrounding the fenestrated capillaries (Brightman and Reese, 1969; cf. Leonhardt, 1980). The basal processes of all tanycytes contain abundant microtubuli and intermediate filaments, and extend variable numbers of lateral protrusions. These processes terminate in conical endfeet whose basal membrane contains orthogonal arrays of particles (Hatton and Ellisman, 1982).

Hypothalamic tanycytes have been studied exten-

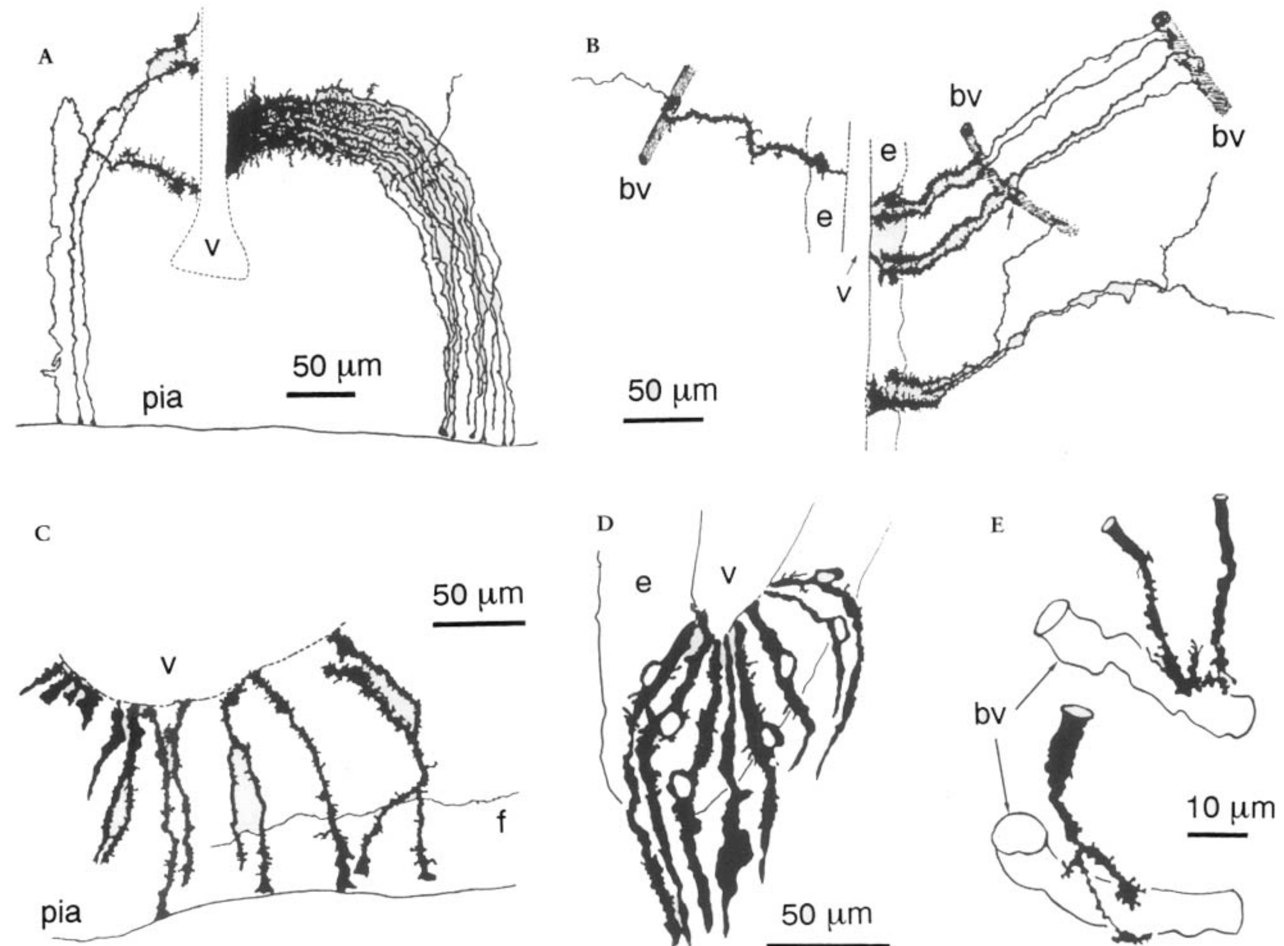

FIG. 4-7. Samples of radial glia in adult mammalian (rat) central nervous system, Golgi impregnation. (A) Ventral diencephalic tanycytes at the level of the anterior hypothalamus. (B) Diencephalic tanycytes at the dorsal level of the ventromedial hypothalamic nucleus. (C) Diencephalic tanycytes of the median eminence. (D) Mesencephalic tanycytes at the aqueduct (only the proximal parts of the cells are drawn). (E) Spinal tanycytes at the central canal (only the distal portions of the basal processes are shown). *e*, ependyma; *v*, ventricle; *bv*, blood vessel. [Figures A, B, C: from Millhouse (1971), with permission; Figure D: from Seress (1980), with permission; Figure E: from Rafols and Goshgarian (1985), with permission.]

sively, and on the basis of their morphology, topography, and metabolism, Akmayev and coworkers (1973) have distinguished several types of hypothalamic tanycytes. α1-Tanycytes (mostly vascular tanycytes) face the ventromedial nucleus (Figure 4-7B), and α2-tanycytes (long pial tanycytes) are found at the level of the arcuate nucleus (Figure 4-7A). The endfeet of β-tanycytes abut the blood vessel system of the pars tuberalis; β1-tanycytes are located in the lateral extensions of the infundibular recess, and β2-tanycytes line the floor of the ventricle (median eminence proper; Figure 4-7C). β-Tanycytes contain abundant lipid inclusions and smooth endoplasmic reticulum (e.g., Rodríguez et al., 1979), together with enzymes of lipid metabolism (Akmayev et al., 1973). The basal processes of β2- (but not β1-) tanycytes receive of up to 100 synapse-like contacts that arise partly from fibers of the tuberohypophyseal tract (e.g., Wittkowski, 1967). These contacts consist of vesicle-containing presynaptic terminals and an unspecialized postsynaptic membrane (Güldner and Wolff, 1973). The endfeet of infundibular tanycytes show varying organelle contents, probably related to their functional state (Rodríguez et al., 1979). These endfeet may occupy variable surface areas on the fenestrated blood vessel plexus, and, thus, regulate the available contact areas of neurohemal axons in dependence on functional requirements (Wittkowski, 1973; Lichtensteiger et al., 1978).

Tanycytes can be more than 20 mm long in the fetal primate brain (Rakic, 1984). Lengths of several millimeters have been reported in the adults of nonmammalian vertebrates (e.g., selachians: Horstmann, 1954; amphibians: Paul, 1967; reptilians: Stensaas and Stensaas, 1968b; birds: Alvarez-Buylla

et al., 1988). In adult mammals, fibrous tanycytes 2 mm long have been described in the floor of the fourth ventricle in rabbits (Felten et al., 1981). Fibrous tanycytes of more than 500 μm in length have been found within the velum medullare of monkeys (Reichenbach, 1990), and in the hypothalamic region of monkeys and rats (Seress, 1980). In contrast, protoplasmic tanycytes are never longer than about 250 μm (Millhouse, 1971; Lichtensteiger et al., 1978; Bruni et al., 1983). The length of these processes may be limited by their capacity to act as "cables" for spatial buffering potassium currents (Reichenbach et al., 1987).

Central Nervous System Radial Glia II: Tanycyte-like Cells of Circumventricular Organs. The ependymal ceiling of the ventricular system is not uniform. Characteristic ependymal specializations, "circumventricular organs," are located at, or near, the median axis of the central nervous system. Their distribution is a legacy of the embryology of the brain: whereas the lateral plates of the neural anlage generate many neurons and differentiate into large tissue blocks, parts of the roof plate, floor plate, and lamina terminalis undergo very restricted neurogenesis. These regions remain "ependymal" and form, in collaboration with blood vessels, peculiar ependymal "organs." Most of these organs lack a blood-brain barrier; in these cases, the ependymocytes are interconnected by apicolateral tight junctions (see also the preceding section *Central Nervous System Radial Glia I . . .*). Circumventricular organs are more common in "lower" vertebrates than in mammals. Space limitations prevent us from reviewing all of the organs here; the interested reader should consult Vigh (1971) for a catalogue of these organs. The choroid plexus is one of the circumventricular organs, and its ependymoglial cells have been already introduced (see the section *Epithelial Ependymocytes*). Details of ependymocytes from two further selected organs are discussed below.

The most intensely studied circumventricular organ is the subcommissural organ. It lies at the border of the diencephalon and mesencephalon and surrounds the dorsal entry of the cerebral aqueduct. The subcommisural organ is present in early development in all vertebrates, but by adulthood it is often substantially reduced or missing (e.g., in humans: Oksche, 1964). In adult heterothermic vertebrates and in fetal birds and mammals, these cells have a tanycyte-like shape; they lose their long basal processes in adult warm-blooded animals (Oksche, 1961). The ultrastructure of these cells indicates a very active secretory function: abundant mitochondria, elaborated endoplasmic reticulum, and secretory vacuoles are tightly packed in their cytoplasm (Figure 4-8A). The main secretory product is a particular glycoprotein, and is released into the ventricular lumen where it aggregates and forms Reissner's fiber. This aggregation is supported and oriented by the kinocilia of the ependymocytes, by the flow of the cerebrospinal fluid, and by stretching forces of the already formed fiber. The fully formed fiber can be up to 50 μm thick and more than 1 m long, since it extends down to the ventriculus terminalis of the spinal cord. A growth rate of several millimeters per day has been observed in most species studied (e.g., Ermisch et al., 1971). Reissner's fiber is also found in *Amphioxus* and in some tunicate larvae, which indicates that this enigmatic strand predates the evolution of the vertebrate nervous system (Bone, 1981). The function of Reissner's fiber is unknown, but there is some evidence that it may be involved in helping to organize the axis of the developing body (Rühle, 1971).

Another circumventricular organ is the saccus vasculosus, which occurs only in fish, as an outgrowth of the hypothalamic floor. The ependyma of this organ consists of coronet cells and "supporting cells" (i.e., microvilli-rich tanycytes), while the neuronal element are cerebrospinal fluid-contact neurons ("pear-shaped cells" in Figure 4-8B). The ependymal cells are interconnected by tight junctions, desmosomes, and zonulae adhaerentes (Jansen and Flight, 1969). Their basal processes form endfeet at the basal lamina that separates the ependyma from the underlying mesenchyme. A complex arrangement of blood vessels, consisting of capillaries and sinuses lies beneath the mesenchymal sheath (Figure 4-8B). The coronet cells owe their name to their apical (flowerlike) protrusions (the "coronets") that consist of up to 20 end-bulbs of modified $9 \times 2 + 0$ cilia. These end-bulbs increase the apical surface area about 800-fold (Jansen, 1975), and seem to consist of convoluted tubules with a diameter of 50 to 150 nm. The apical cytoplasm of these cells is tightly packed with smooth endoplasmic reticulum. The basal cytoplasm contains many mitochondria and various types of granules. Coronet cells are targets of synaptoid contacts (Jansen and Flight, 1969). It has been suggested that coronet cells have a secretory function, and possibly assist osmoregulation (e.g., von Mecklenburg, 1973), by cation transport (Jansen, 1975).

Central Nervous System Radial Glia III: Retinal Müller Cells. Insofar as the retinas of both lateral and pineal/parietal eyes are embryonic outgrowths of the diencephalon, their radial glial cells belong to the diencephalic tanycyte group; on the other hand, eyes

may be considered to be circumventricular organs (Leonhardt, 1980). The radial fibers of lateral eye glia were discovered by H. Müller in 1851, and the cells now bear his name. They appear to be present in the retinas of all vertebrates, including those of agnatha (Rubinson, 1990).

Similar cells have been described in the parietal/frontal eyes of lizards and frogs (Eakin, 1973; Engbretson and Linser, 1991) (see Figures 4-8C, and 4-9A) but not in birds and mammals, where the pineal is differentiated as an endocrine gland and does not show the structure of a sensory epithelium. In reptilian parietal eyes, the apical border of the supporting cells bears microvilli and cilia that project into the lumen of the organ. Their apical cytoplasm contains numerous mitochondria, filaments, vesicles, vacuoles, lipoid bodies, and a Golgi complex. The cells form tight and adherent junctions with adjacent cells. The cells are bipolar, and extend a basal process that terminates in a flattened endfoot at the basal lamina covering the underlying mesenchymal tissue. Like retinal pigment epithelium cells, the supportive cells of the reptilian parietal eye contain pigment granules that are probably composed of melanin (Eakin, 1973; Engbretson and Linser, 1991). On the other hand, they bear biochemical similarities to Müller cells of the lateral eyes.

Müller cells are bipolar tanycytes whose somata lie within the inner nuclear layer (where they may form a distinct median sublayer in some species). They constitute the principal glia of the retina and span its entire thickness. Although Müller cells from different species vary considerably in shape (Figure 4-9B–O), some features are fairly universal. At the level of the outer limiting membrane, Müller cells extend apical microvilli into the subretinal space, between the inner segments of photoreceptor cells (Figures 4-3E, 4-9, 4-10). In some species, Müller cells also possess a cilium (Ennis and Kunz, 1986). The length and number of microvilli vary between species, probably in inverse relation to the degree of vascularization (Uga and Smelser, 1973; see, however, Dreher et al., 1992). Apicolaterally, Müller cells are connected to their neighboring Müller and photoreceptor cells by specialized junctions to form the outer limiting "membrane." In most vertebrate species studied these junctions are zonulae adhaerentes or (in fish) tight junctions. However, amphibian Müller cells are connected instead by intermediate junctions, and (in frogs and toads) by gap junctions (Uga and Smelser, 1973) that permit extensive electrical coupling (Attwell et al., 1985). Although human Müller cells are reported to express gap junctions in the inner retina (Reale et al., 1978), neither

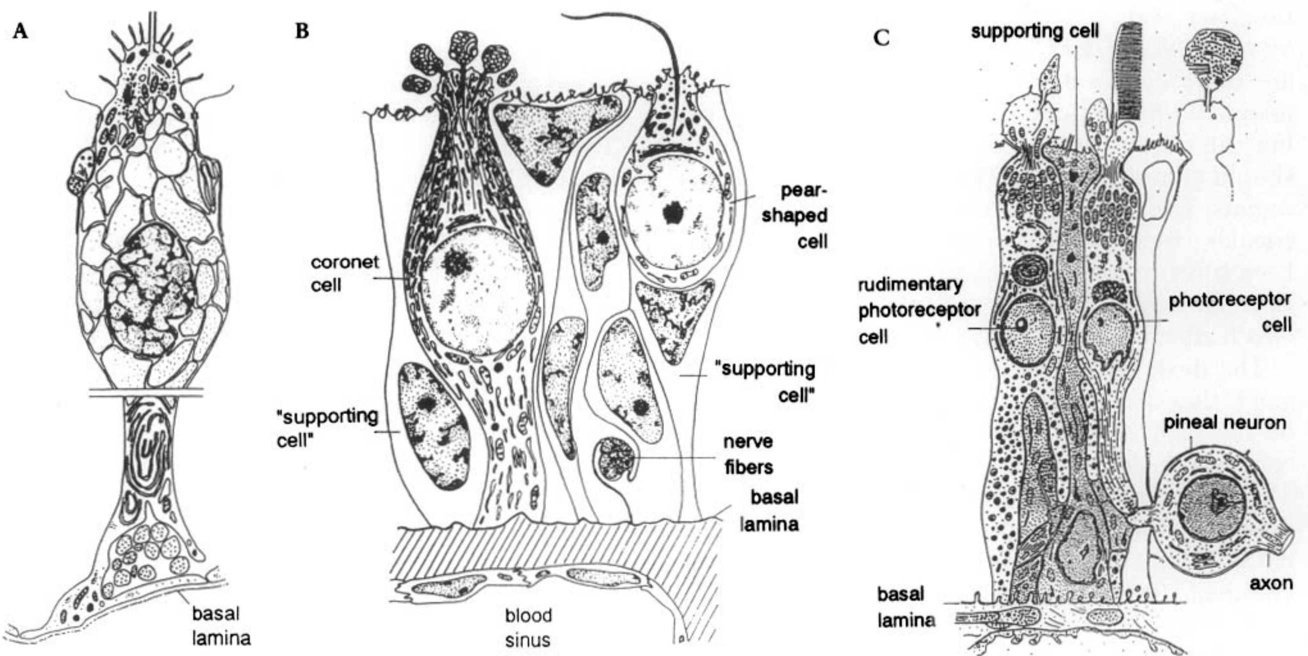

FIG. 4-8. Specialized ependymal cells in the "midline organs." (A) Cell of the subcommissural organ of *Bombina variegata* (toad, anuran amphibia). [From Altner (1968), with permission]. (B) Epithelium of the saccus vasculosus of *Spinax niger* (selachian fish), containing coronet cells, pear-shaped cells, and "supporting" ependymal cells. [From Graf von Harrach (1970) with permission.] (C) Parietal organ of the adult wall lizard (*Lacerta muralis*), illustrating the sensory epithelium. [From Collin and Oksche (1981), with permission.]

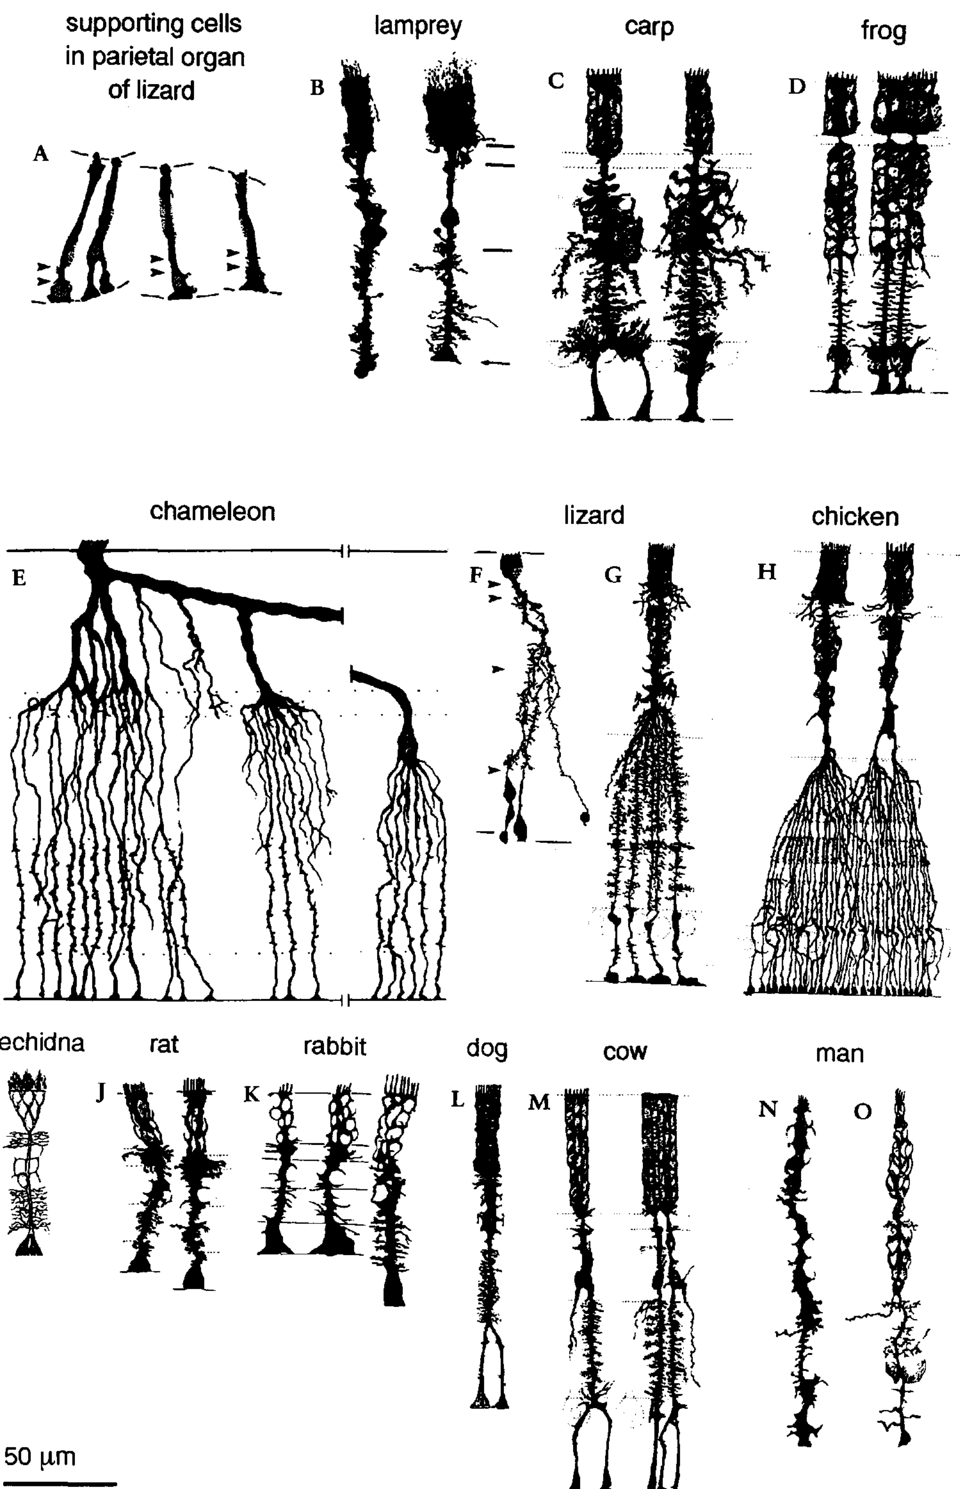

FIG. 4-9. Retinal radial glial cells. Shown are supporting cells of lizard parietal organ (*top left*) and Müller cells of various vertebrate species. Golgi impregnation, with the exception of the *Echidna* Müller cell that is a camera-lucida drawing of an immunocytochemically stained specimen. Note that the chameleon Müller cell is only partly shown; the transversal process is interrupted for a length of several hundred micrometers. At the top is the apical process of the cells (reaching the subretinal space), at the bottom are the vitread endfeet. The calibrating bar gives only an approximate idea of different cell sizes, since Ramón y Cajal's and Dogiels' drawings are without calibration. gap nor tight junctions have been unequivocally demonstrated in the apicolateral membrane of mammalian Müller cells *in situ*. Gap junctions between Müller cells and astrocytes have been demonstrated in the rabbit retina with dye-coupling (Robinson, 1992: Robinson et al., 1992), but Müller cells are never dye-coupled to each other.

Müller cells send side branches into the two plexiform (synaptic) layers, where they form sheaths around neuronal processes and synapses, particularly around the photoreceptor pedicles in the outer plexiform layer (Reichenbach et al., 1989) (see Figures 4-3E, 4-9, and 4-10). They wrap most, but not all, neuronal profiles in the plexiform layers. In the nuclear layers, the lamellar processes of Müller cells form basketlike structures that envelop the cell bodies of neuronal cells (Ramón y Cajal, 1892; Hama et al., 1978; Reichenbach et al., 1988, 1989; Dreher et al., 1992) (Figures 4-9 and 4-10). Müller cells extend smooth and sometimes rather long processes through the nerve fiber layer. Like astrocytes at the nodes of Ranvier, Müller cells send side branches that form finger-like coronae of fine processes abutting node-like specializations of nerve fibers (Hildebrand and Waxman, 1984; Reichenbach et al., 1988).

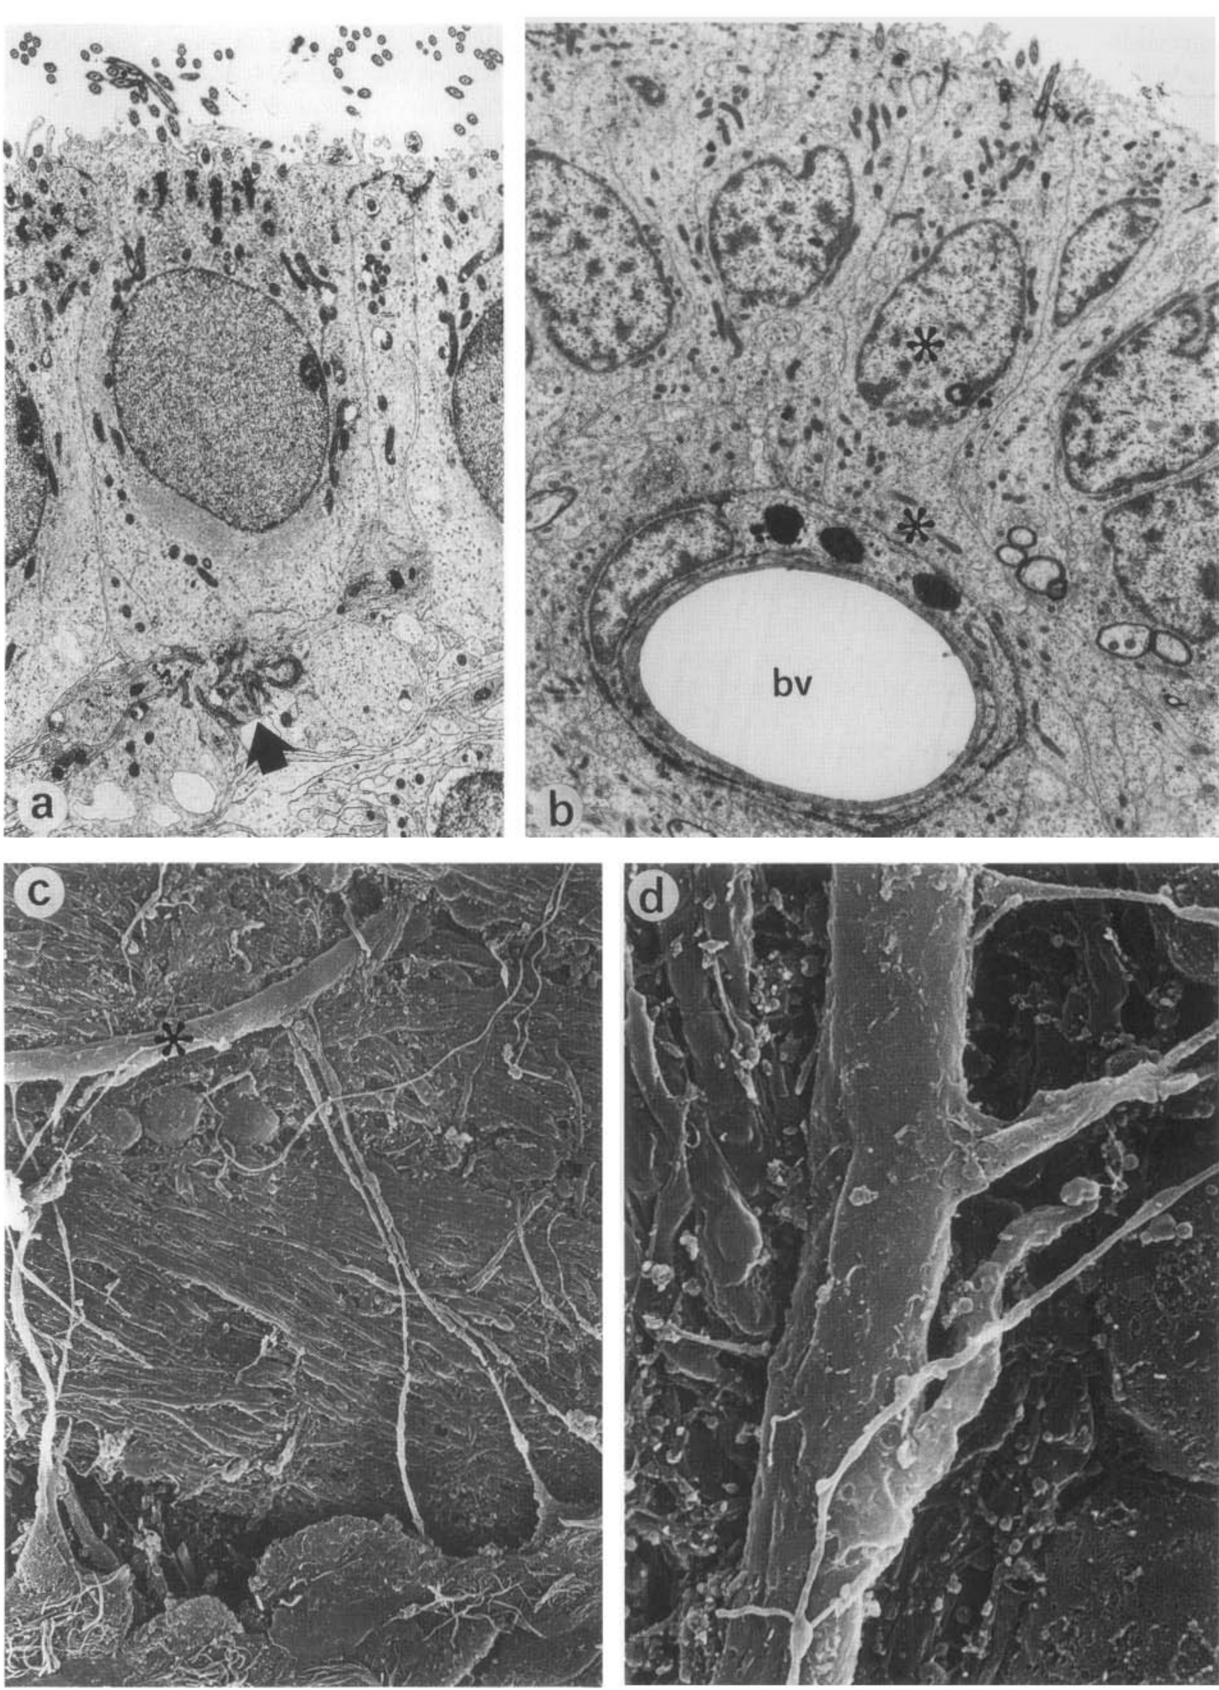
The basal end of each Müller cell trunk terminates in a funnel-shaped endfoot, which lies adjacent to the inner limiting membrane. This membrane is a basal lamina that is at least partly produced by Müller cells. Müller cell endfoot plates form a mosaic that can be revealed by silver impregnation (Wolter, 1961), scanning electron microscopy (Masutani-Noda and Yamada, 1983), immunocytochemistry (Dreher et al., 1988), and freeze-fracture electron microscopy (Wolburg and Berg, 1988; Richter et al., 1990). Each endfoot extends some side branches that overlap with similar branches from neighboring endfeet. The vitread endfoot membranes of all vertebrates except anurans express orthogonal arrays of membrane particles (Reale et al., 1974; Wolburg and Berg, 1988; Richter et al., 1990; Wolburg et al., 1992). In species with vascular retinas, the same membrane specializations are found where Müller cells form *en-passant* endfeet onto retinal blood vessels (Wolburg and Berg, 1988). Some Müller cells have been observed that did not reach the inner limiting membrane but terminated at a large intraretinal blood vessel (Reichenbach et al., 1992a).

As a rule, Müller cells in avascular retinas have mitochondria only in the scleradmost portion of their cytoplasm (see, e.g., rabbit: Figure 4-10), whereas in retinas with intra- or epiretinal blood vessels, mitochondria are also found in their vitread endfeet (Uga and Smelser, 1973). Amphibian Müller cells are exceptional in several respects (see above). They express lateral membrane infoldings near both outer and inner limiting membranes (Uga and Smelser 1973) (see also Figure 4-3E), and large extracellular spaces occur around their endfeet, (Lasansky and Wald, 1962). Reptilian and avian Müller cells are conspicuous by the elaborate subdivision of their vitread process into many branches where the trunk enters the inner plexiform layer (Figure 4-9). In chameleons, Müller cell trunks follow a tangential course near the fovea, but these cells also give rise to supplementary trunks that course radially toward the inner limiting membrane (Ramón y Cajal, 1911; Prada et al., 1979) (Figure 4-9E). There are often striking quantitative and qualitative differences between Müller cells that vary systematically with eccentricity across a single retina (Dogiel, 1893; Prada et al., 1979; Prada et al., 1989; Reichenbach and Wohlrab, 1986; Reichenbach et al., 1988; Reichenbach et al., 1989; Robinson and Dreher, 1990; Dreher et al., 1992) (see also Figure 4-14).

Ependyma *s. str.*; Ciliated Ependymocytes. In adult mammals, the ventricular lining is mainly composed of cuboid ciliated ependymocytes. These cells may be columnar with a height of up to 15 μm or as flat as 0.1 μm, depending on location; they tend to be taller over gray matter than white matter. In hydrocephalus they become very flattened (Weller et al., 1971).

The apical surface of an ependymocyte is characterized by variable numbers of microvilli and protrusions, and 12 to 60 kinocilia, which vary in number according to the species (Brightman and Palay, 1963) (Figures 4-11 and 4-12). The cilia are 10 to 20 μm long, and are of the $9 \times 2 + 2$ type. These cilia beat rhythmically at a frequency of about 200 oscillations per minute (Singer and Goodman, 1966) and appear to assist the rostrocaudad flow of cerebrospinal fluid.

Ependymocytes are connected by apicolateral zonulae adhaerentes and gap junctions. The fact that ciliated ependymocytes lack tight junctions permits free exchange between the extracellular space of the brain and the cerebrospinal fluid (e.g., Brightman and Reese, 1969). Ependymocytes have a cytoplasm that is rich in intermediate filaments and large mitochondria. Their basal surface terminates directly onto the basal lamina of a blood vessel (Figure 4-11B), or onto a "basement membrane labyrinth" (Figure 4-11A). Such labyrinths are the remnants of an embryonic vascular network in the subventricular zone (Leonhardt, 1970; Booz et al., 1974). Fine basal processes of ciliated ependymocytes may extend over considerable distances to meet the basal lamina of sube-



a

c
d

pendymal blood vessels (Hirano and Zimmerman, 1967); in contrast to those of tanycytes, these basal processes are oriented transversely rather than orthogonally to the ependymal surface (Inokuchi et al., 1988) (Figure 4-11C, D). Rodríguez et al. (1985) state that every ependymocyte contacts a basal lamina at its basal pole.

GENERAL FEATURES OF EPENDYMOGLIAL CELL PROCESSES

Types of Ependymal Cell Processes as Determined by Contacts to Different Microenvironmental Compartments

When the structure and ultrastructure of various ependymal cell types is compared, a series of striking similarities becomes apparent. It has been suggested by Reichenbach (1989) that contact to similar types of microenvironment may induce similar features of the contacting cell processes. Figure 4-13 gives a survey on the diversity of types of processes that, in principle, may occur on ependymoglial cells; for a review of functional specializations of these processes, see Reichenbach (1989).

Type I: The Apical Pole of Neural Epithelium. By definition, a process of type I (i.e., a process contributing to the apical pole of the neuroepithelium) is an obligatory feature of every ependymoglial or ependymoglia-like cell. Usually, its tip faces a fluid lumen or space, into which it extends many microvilli. The apical pole contains abundant mitochondria, features that indicate high metabolic activity, which is presumably related to active exchange of substances with the luminal fluid. The supporting cells of the inner ear (whose apical pole is confronted to endolymph resembling the intracellular milieu in many respects) seem to be an exception to this pattern, since apical microvilli and mitochondria are rare if not absent (Figure 4-3D). A further characteristic of apical processes in some but not all ependymoglia are kinocilia of the 9 × 2 + 2 type. These kinocilia seem to be phylogenetically conservative property, since they are present in ependymoglia-like cells of primitive deuterostomian nervous systems (Figure 4-3A, and 4-5A), as well as in cells of the "ciliary bands" of deuterostomian larvae (Figure 4-2) that may resemble the evolutionary precursors of the vertebrate neural tube (e.g., Lacalli et al., 1990; Crowther and Whittaker, 1992).

Finally, type I processes are interconnected by various types of apicolateral junctions. These (in particular, desmosomes) are general "markers" of virtually all epithelial cells and occur very early in development (Revel and Brown, 1976). Thus, their expression may be genetically determined. On the other hand, their nature varies considerably depending on the local microenvironment. In regions where no endothelial blood-brain barrier exists (e.g., most circumventricular organs; retinal pigment epithelium), but not elsewhere, ependymoglial cells form a cerebrospinal fluid-brain barrier by the expression of tight junctions (cf. the situation in elasmobranchs; see Chapter 6). Apicolateral gap junctions occur between Müller cells in frogs but not in mammals; when, however, rabbit Müller cells form homogeneous cultures *in vitro*, gap and even tight junctions can be observed (Wolburg et al., 1990).

There are further examples of modification of process-specific features. When the basal pole of retinal glial (Müller) cells is directly exposed to the vitreous humor (after basal lamina defects in retinal wounds) the cells send microvilli into the lumen of the eye (Foos and Gloor, 1975; Miller et al., 1986). Retinal pigment epithelium cells proliferating under areas of retinal detachment may lose their basal lamina contact and face the subretinal fluid round about; in this case, their entire surface is covered by microvilli (Anderson et al., 1983).

Thus, the microenvironment seems to determine not only the occurrence but also many of the particular features of type I processes.

Type II: The Basal Mesenchymal Contact. Whereas the contact with the apical surface of the neural epithelium is a primary feature of neuroectodermal cells that is retained even during mitotic cell proliferation (which principally occurs at the ventricular surface) (Sauer, 1935), the basal pole of the epithelium can be reached only by the growth of basal processes. From cell culture experiments, there is some evi-

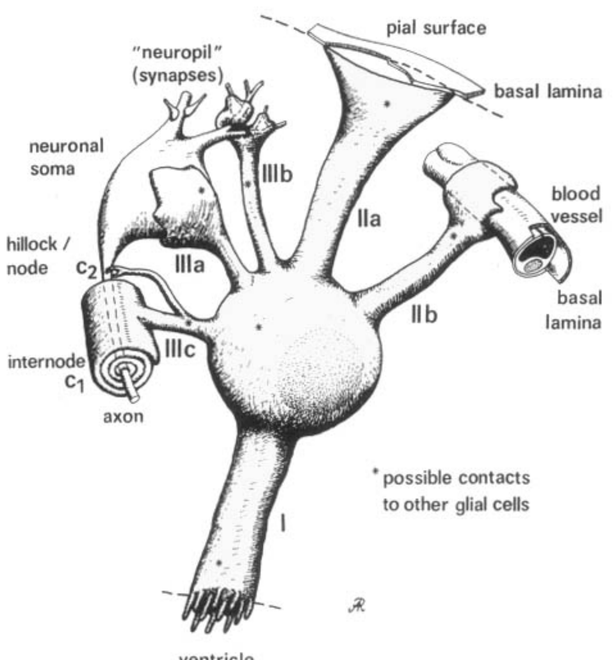

FIG. 4-13. "Idealized" ependymoglial cell expressing all types of contacts to microenvironmental compartments that such a cell can have. The three types of processes are (*I*) abutting the ventricular surface, (*II*) abutting a basal lamina, either of the pia mater (*IIa*) or of a blood vessel (*IIb*), and (*III*) ensheathing neuronal compartments as somata (*IIIa*), synaptic neuropil (*IIIb*), or axons (*IIIc*). [From Reichenbach (1989), with permission.]

dence of an inherent tendency toward bipolar growth by ependymoglia (e.g., Hatten, 1984) that may be stimulated by neighboring neurons (Hatten, 1985); on the other hand, mesenchymal cells seem to exert a chemoattractive influence on ependymoglial cell processes (D. Hartmann, personal communication, Kiel, 1994). In any case, the basal processes of ependymoglia form endfeet onto the basal lamina of the mesenchymal layer(s) underlying the nervous epithelium (type IIa), or the basal lamina of blood vessels (type IIb) (see Figure 4-13). The latter occurs more frequently at later stages of development when the tissue becomes thicker and vascularized.

Endfoot (footplate) membranes are connected to the basal lamina by hemidesmosomes, and express orthogonal arrays of intramembrane particles (Reale et al., 1974; Hatton and Ellisman, 1982; see also Chapter 41, this volume). The occurrence of vesicles concerned with endo-, exo-, or pinocytosis and coated pits indicates active material exchange with the compartment behind the mesenchymal basal lamina (i.e., blood plasma, vitreous body, subarachnoidal fluid, or perilymph). Ependymoglial type II processes are characterized by a cytoskeleton that is reinforced with abundant intermediate filaments. These filaments consist primarily of vimentin when the endfoot is in contact with cerebrospinal fluid or vitreous humor but of glial fibrillary protein when a blood vessel is contacted (Pixley and De Vellis, 1984; see also Chapter 43, this volume). Supporting cells of invertebrates (Bargmann et al., 1962) as well as those in the vertebrate peripheral nervous system (Angelborg and Engström, 1972) may contain very particular filaments.

When, under pathological or experimental conditions, apicolateral membranes of retinal pigment epithelium cells (Korte et al., 1986), Müller cells (Korte et al., 1992), or ependymocytes (Rosenstein and Brightman, 1979) are confronted with mesenchyma, they lose their original features and develop an endfootlike structure. This response suggests that mesenchymal contact (collagen?, laminin?) inhibits cell proliferation and process growth, and stimulates filament formation (Goetschy et al., 1987) and the production of basal lamina (Crawford, 1983; von Knebel Doeberitz et al., 1986). Thus, as was discussed for type I processes, the microenvironment seems to determine not only the occurrence but also much of the particular features of type II processes.

Type III: The Contact with Neurons. Type III processes are characterized by the formation of flat or lamellar sheaths that enclose neuronal somata (IIIa), synapses (IIIb), or axonal internodes ($IIIc_1$), or by fingerlike extensions (Carlstedt, 1977; Waxman, 1983) that contact the nodal specializations of axons ($IIIc_2$) (see Figure 4-13). These processes may act as stores of sodium or calcium ions (e.g., Gambetti et al., 1975).

In contrast to type I and type II contacts, which may establish early in ontogeny, specialized type III processes cannot be elaborated until neurons have completed their differentiation (Waxman et al., 1983). Indeed, the formation of such processes may be triggered by the onset of neuronal activity (Reichenbach and Reichelt, 1986), and their growth may be attracted (or repelled) by signals from active neurons. Potassium ions (Reichenbach and Reichelt, 1986; Reichelt et al., 1989) and neurotransmitters, such as glutamate (Cornell-Bell et al., 1990) and γ-aminobutyric acid (GABA) (Kettenmann et al., 1991), have been demonstrated or suggested as such neuronal signals. Several second messenger systems seem to be involved. Protein kinase C accelerates protein synthesis-dependent growth of long, branching processes (Althaus et al., 1991). In contrast, protein kinase A induces growth of short processes which extend flat membraneous sheaths from their growth cones; this might be important for ensheathing of neuronal elements (Althaus et al., 1990). A survey on the cascade(s) of signal trans-

mission has been provided by Arenander et al. (1988).

As was the case for type I and II processes, the microenvironment seems to determine not only the occurrence but also much of the particular features of type III processes.

Shape and Shaping of Cell Processes

It is long known that fibrous glia, which are found mainly in the white matter, can be distinguished from protoplasmic glia, which reside mostly in the gray matter. More recently, "velate astrocytes" were recognized by Chan-Palay and Palay (1972). These cells give rise to "bubble"- or basket-like sheaths around somata of small neurons. It has been pointed out that if it is long enough, the character of a single glial cell process can change from "protoplasmic" to "fibrous" as it passes from gray to white matter (Millhouse, 1971; Miller and Liuzzi, 1986) (Figure 4-7A). Müller cells may express up to three different morphologies as their processes pass through the various retinal layers. This variation is particularly evident in the rabbit retina, which contains true "white matter" in the form of a myelinated nerve fiber layer (Magelhães and Coimbra, 1972; Reichenbach et al., 1989; Figures 4-3E, 4-9, 4-10, and 4-14). Thus, within the outer and inner nuclear layers, Müller cell processes (and somata) are of the "velate" type, whereas in the plexiform (synaptic) layers they extend many fine side branches, and are "protoplasmic" in nature. Finally, within the nerve fiber layer Müller cell processes are smooth and "fibrous." Thus, glial cell processes seem to be shaped to a

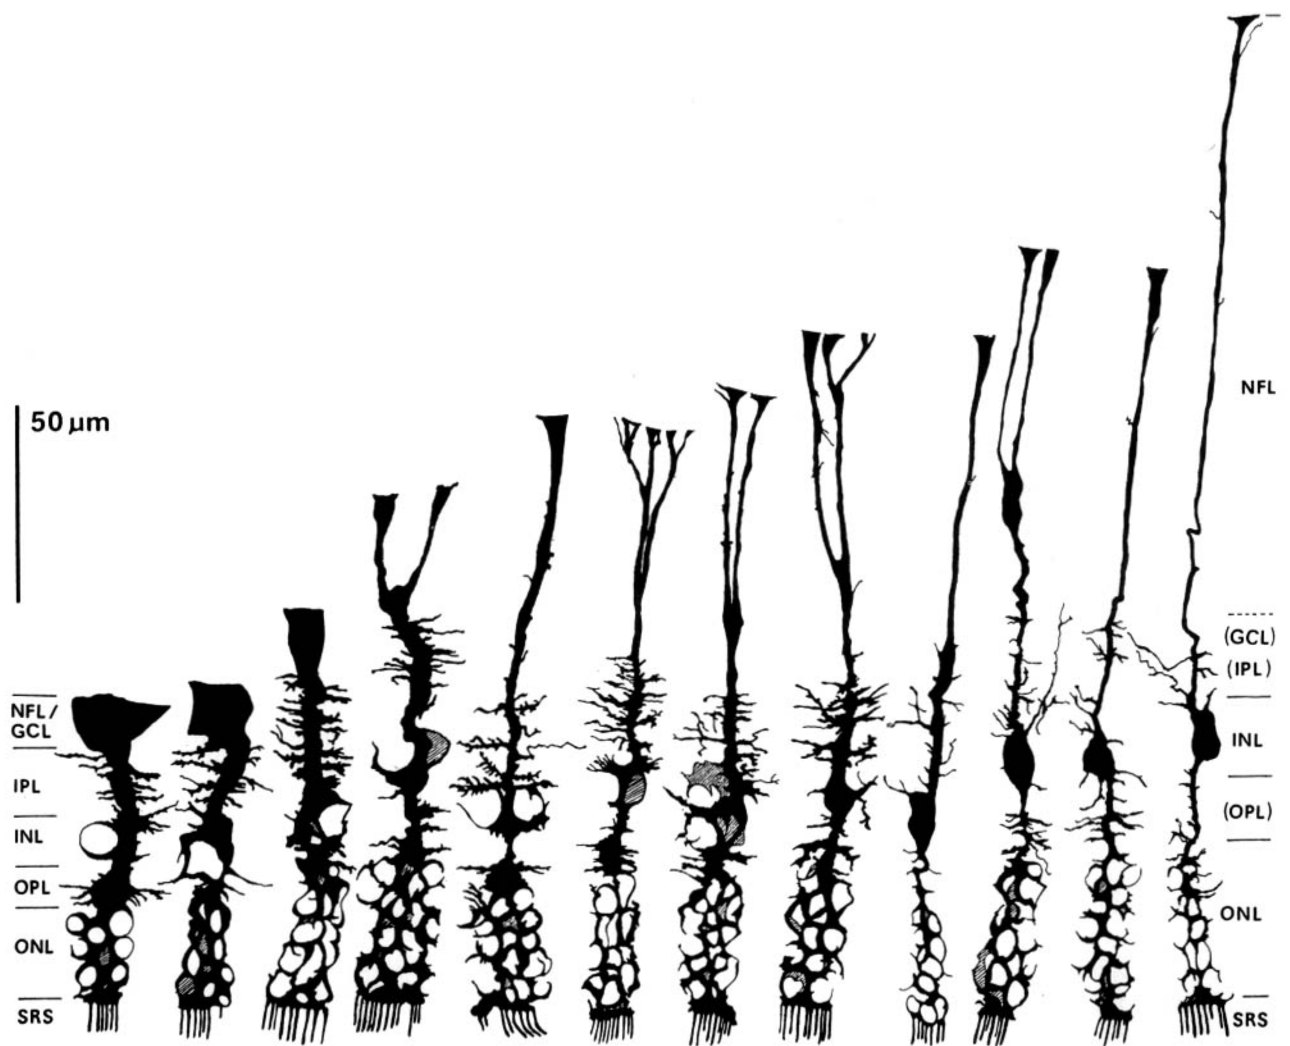

FIG. 4-14. Golgi-impregnated Müller cells from various regions of the rabbit retina (*left side*); far periphery (*right side*); medullary rays (*center*). *SRS*, subretinal space; see caption of Figure 4-10 for other symbols. [From Reichenbach et al. (1989), with permission.]

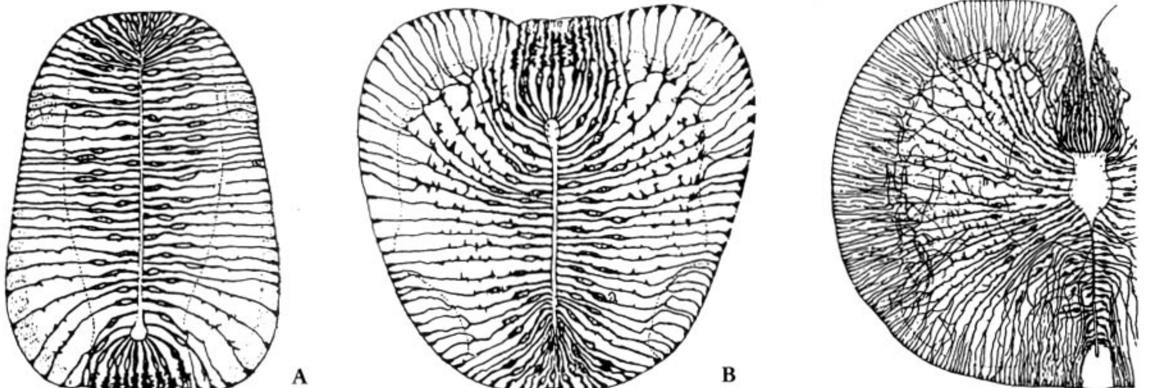

FIG. 4-15. Cross sections through the embryonic spinal cord of (A) chicken (3rd day of incubation = *E3*), (B) chicken (*E5*), and (C) human embryo, 44 mm long. Camera-lucida drawings of Golgi-impregnated neuroepithelial-radial glial cells. Note that the figures are not shown at equal magnification [From Ramón y Cajal (1911).]

large extent by their local (neuronal) environment, as if the glial side branches had been grown into the available interspaces between established neuronal compartments.

This principle is nicely illustrated by the fact that radial glia born after a marginal zone (i.e., future white matter) has formed, show characteristic splitting of their trunks as they enter this zone (Figures 4-6, 4-9, 4-14, and 4-15). This pattern suggests that axon bundles resist the ingrowth of glial processes, and that the growing tips of radial glia respond by issuing several sprouts that try to find a way around these obstacles. Similarly, in reptilian and avian retinas, where a thick inner plexiform layer is elaborated early in ontogeny, the Müller cell trunks split into numerous trunklets as they enter the inner plexiform layer (Figures 4-9F, H). Furthermore, if the viscosity of the medium is increased by addition of agarose (0.1 to 1.5%), the process growth of cultured glial cells is greatly impaired (H. Althaus, personal communication, Göttingen, 1993). While the preceding observations suggest that (at least, growing) glial cell processes are pliable compared with those of neurons, specialized ependymoglia-like cells (e.g., in Corti's organ) seem to provide mechanical support to neurons.

The shape of cell processes greatly influences their surface:volume ratio, which can be translated as membrane:cytoplasm ratio, and which can be estimated from the fractal dimension *D*, describing the surface complexity of a structure (Reichenbach et al., 1992b). Protoplasmic processes have surface:volume ratios in the order of 12 to 18 μm^{-1}, whereas fibrous processes have much lower surface:volume ratios of less than 4 μm^{-1} (Rasmussen, 1975; Wolff, 1976; Grab et al., 1983; Reichenbach et al., 1988, unpublished results). Velate processes seem to reach the highest surface:volume levels of 20 to 25 μm^{-1} (Rasmussen, 1975; Reichenbach et al., 1988, 1992b). Interestingly, there exists an indirect proportionality between the surface complexity (i.e., surface:volume ratio) and the length of glial cell processes (Siegel et al., 1991; Reichenbach et al., 1992b). This relationship may indicate that the absolute membrane surface area a glial cell can produce is limited (perhaps, by metabolic constraints).

A similar relationship exists concerning the diameter of radial glial cell processes; in a given species (and tissue) and at a given developmental stage, there is an inverse correlation between process length and diameter (Ugrumov et al., 1979; Bruni et al., 1983; Reichenbach and Wohlrab, 1986; Hanke and Reichenbach, 1987; Reichenbach et al., 1987) (Figure 4-14); the absolute diameter ranges between several microns and (in embryonic radial glia) less than 0.4 μm. When rat radial glial cells of very different lengths are compared at the same embryonic stage, their absolute volumes are found to be almost the same (Reichenbach et al., 1987). It seems as though ependymoglia require a certain period to produce a given cytoplasmic volume. Since they are attached to both surfaces of the neuroepithelium, they may be stretched differently by local tissue growth rates, but such elongation occurs at the expense of process diameter until new material can be synthesized. Such "passive" growth mechanisms have been studied by Jaeger (1988), and might be mediated by stretch-activated ion channels that have been demonstrated to occur in ependymoglial cells (Christensen, 1987). Generally, older cells have larger volumes than young cells (Reichenbach and Reichelt, 1986; Hanke and Reichenbach, 1987).

Rapid, reversible, protein synthesis-independent changes in cytoskeleton and cell shape are induced

by cyclic adenosine monophosphate (Ciesielski-Treska et al., 1984). They may be involved in some of the dynamic interactions with neuronal cells that are discussed in the next section.

Dynamic Properties: Functional Interactions with Neurons

Ultrastructural and even structural features of ependymoglial cells are by no means constant. Physiological stimulation of sensory epithelia and brain compartments evokes specific reactions among ependymoglia. In the olfactory epithelium for example, odorant stimulation evokes secretory activity by the sustentacular cells (Getchell et al., 1984). Stimulation by hormones or by exsiccation of neurons in the tuberohypophyseal system leads to changes in the covering of blood vessels by tanycytic endfeet (Wittkowski, 1973; Lichtensteiger et al., 1978), the ultrastructure of which changes with the physiological state (Rodríguez et al., 1979). In rhesus monkeys, the structure of hypothalamic tanycytes differs between male and female animals; moreover, the apical protrusions of tanycytes in females change their size and number depending on the estrous cycle (Knowles and Anand-Kumar, 1969). Disc shedding of photoreceptor outer segments occurs with a circadian rhythm, and is reflected by cyclic changes in phagocytotic metabolism of retinal pigment epithelial cells (cf. Steinberg, 1985). Adaptation to bright light causes retraction of pigment granules toward the basal pole in retinal pigment epithelium cells as well as in supporting cells of the reptilian parietal eye (Ali, 1971).

Furthermore, many lesions of neuronal tissue precipitate structural changes among the ependymoglia. In retinal detachment for example, the nuclei of Müller cells migrate out of the inner nuclear layer, and cells dramatically change their shape (Anderson et al., 1983). Examples of such structural adaptations of ependymoglial cell processes to changed microenvironments are also mentioned in the sections *Type I* . . . and *Type II* . . . above. In summarizing these few examples it may be stated that ependymoglial cells are continuously adaptating to the changing needs of the neuronal tissue.

DEVELOPMENTAL AFFINITIES OF EPENDYMOGLIA

In all vertebrates, the central nervous system arises from an ectodermal neural plate, and the peripheral sensory epithelia arise from ectodermal (or endodermal) placodes. By the time that the first neurons in the central nervous system become postmitotic, the tissue consists of a ventricular (or matrix) zone formed by cell nuclei undergoing interkinetic migration, and a marginal zone (*Randschleier*) formed by the neurites of first postmitotic neurons. The latter (Cajal-Retzius cells of neocortex, motoneurons of spinal cord, ganglion cells of retina, etc.) are found between both zones (in the "mantle zone"); some cerebrospinal fluid-contact neurons also seem to be generated early (retinal cone photoreceptors: Robinson, 1991; spinal cord sensory cells: Roberts and Clarke, 1982; Dale et al., 1987). At this stage, two types of radially oriented cells span the width of the epithelium: neuroepithelial stem cells and young radial glial cells (Levitt and Rakic, 1980; Eckenhoff and Rakic, 1984). Thus, the structure of the early vertebrate neuroepithelium closely resembles that of the primitive deuterostomian nervous system (see Figures 4-1 and 4-2).

Initially (Figure 4-15A) embryonic radial glial cells are not readily discriminable from neuroepithelial stem cells. Radial glial cells begin their morphological differentiation by sprouting lateral protrusions from their trunks (Figure 4-15B, C). Somewhat later, some of the cells begin to lose their contact to the ventricular system (Figure 4-15C) and, thus, are no longer members of the ependymoglial family (cf. Chapter 49).

It is difficult to determine when radial glial cells become committed from their neuroepithelial precursors, since their differentiation is rather conservative. Initially, there are no obvious morphological changes, and the cells continue to express a series of marker proteins that are already expressed by primitive neuroepithelial cells such as vimentin (Lemmon, 1986), nestin (Hockfield and McKay, 1985), antigen for RC1 antibody (Misson et al., 1988), intermediate filament-associated protein a-400 (Chabot and Vincent, 1990), and carbonic anhydrase (Linser and Moscona, 1982).

Mature ependymoglia (or ependymoglia-like cells) have sometimes been reported to act as precursor cells for neurons. This has been observed during regeneration of spinal cord (Egar and Singer, 1972), for neuromast sensory cells (Balak et al., 1990), cochlear hair cells (Corwin and Cotanche, 1988; Raphael, 1992), and also taste buds (Delay et al., 1986). Furthermore, neurogenesis from presumed ependymoglia has been reported in the brains of adult amphibians, reptilians (Polenov et al., 1972; Lopez-Garcia et al., 1988), and even birds (Alvarez-Buylla et al., 1990; cf. Alvarez-Buylla, 1990). These observations suggest that there is only a small (and often reversible) transition between neuroepithelial stem cells and radial glia.

In any case, radial glial cells characteristically are involved in the radial organization of young neurons within the nervous tissue. One such case is the olfac-

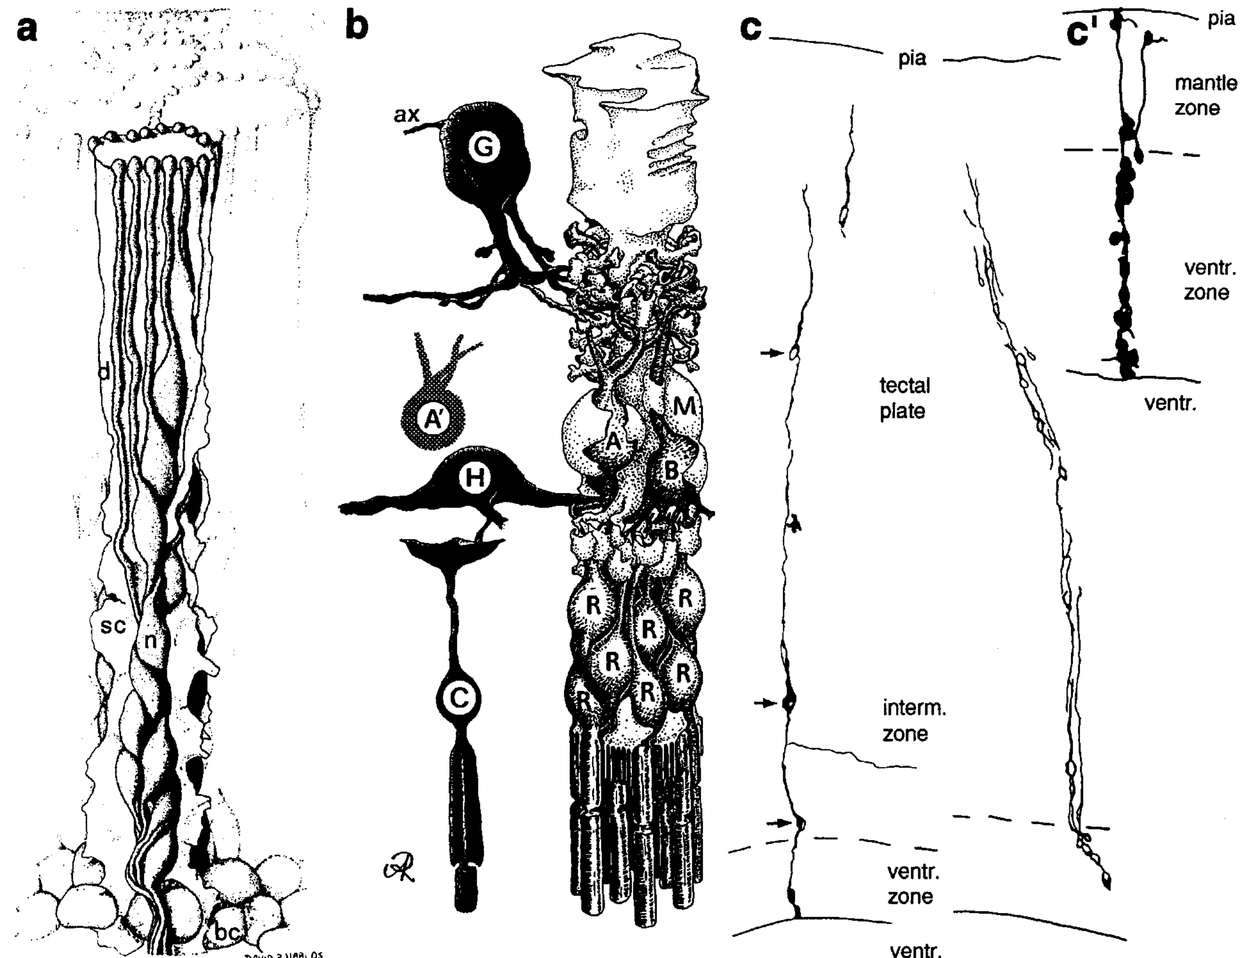

FIG. 4-16. The role of radial glial cells in organization of columnar units. (A) Adult rodent olfactory epithelium; shown is the columnar arrangement of the mature neurons (*n*) and their dendrites (*d*) around the supporting cells (*sc*); *bc*, basal cells that are the stem cells of the epithelium. (B) Adult rabbit retina; a columnar unit of neurons (*R*, rod photoreceptors; *B*, bipolar cells; *A*, amacrine cells) is ensheathed by cytoplasmic extensions from a Müller cell (*M*); these cells are probably the progeny of common precursor cell. Other types of neurons (*G*, ganglion cells; *H*, horizontal cells; *C*, cone photoreceptors, and some amacrine cells *A'*) are born earlier in ontogenesis, by another type of precursor cell. (C), (C')Camera-lucida drawings of cell clones in embryonic chicken optic tectum; each clone consists of one radial glial cell and up to 15 neuronal (or nonradial glial) cells that climb along the radial glial cell process. Retroviral vectors were introduced at *E4* (Figure C) or *E3* (Figure C') and clones demonstrated at *E10* (Figure C), or *E5* (Figure C'). [Figure A: from Graziadei and Monti Graziadei (1979), with permission; Figure B: from Reichenbach et al. (1993), with permission; Figures C and C': from Gray and Sanes (1992 and 1991), respectively, with permission.]

tory epithelium where receptor neurons are renewed from basal cells throughout life and form columnar units together with a supporting cell (Graziadei and Monti Graziadei, 1979) (Figure 4-16a).

In the mammalian retina, an early proliferative phase produces several types of "primary" neurons (black in Figure 4-16B). In a second proliferative phase, columnar clones are generated each from a common progenitor (white in Figure 4-16B); such a clone consists of one Müller cell and a defined number of rod photoreceptors, bipolar cells, and amacrine cells (e.g., Turner and Cepko, 1987; cf. Reichenbach et al., 1993). These neurons become ensheathed by lateral cytoplasmic excrescences of the Müller cell, and seem to form a metabolic and functional unit together with this cell (for detailed arguments, see Reichenbach et al., 1993). A similar phenomenon has been observed in the avian optic tectum (Gray and Sanes, 1991, 1992); progenitor cells resembling radial glial cells produce cell clones that consist of one radial glial cell and up to 15 neuronal (and nonradial glial) cells. The latter migrate along the radial glial process to reach the tectal plate (Figure 4-16C, C'). Obviously, this is a general mechanism in the mammalian central nervous system; see also Chapter 49.

The authors wish to thank Prof. H. Leonhardt (Kiel University), Dr. H. Althaus (Max Planck Institute Göttigen), and Prof. W. Wittkowski (Münster University) for helpful discussions.

5 Microglial cells

WOLFGANG J. STREIT

Microglial cell numbers are often said to range from 5 to 20% of the entire central nervous system glial cell population (e.g., Kreutzberg, 1987). As a conservative estimate, assuming that microglia represent 10% of the total glial cell pool and knowing that there are at least 10 times as many glial cells as neurons in the central nervous system, it is apparent that there are at least as many microglia as there are neurons. This simple calculation is astonishing only insofar as the very existence of microglial cells was questioned by some scientists until recently.

Research on microglia has grown significantly during the past decade. This positive trend can be attributed largely to the development of reliable histological methods for identifying the cells in tissue sections using light microscopy. Most of these methods, which are described in this chapter, can also be carried to the electron microscopic level, allowing verification of microglial identity through direct comparison of the presence of a specific marker with ultrastructural morphology. Before the advent of microglia-specific markers, electron microscopy was almost always needed for positive identification, using solely morphological criteria. An excellent description of the ultrastructural morphology of microglial cells can be found in Peters et al. (1991). An assortment of light microscopical techniques are now available that permit easy identification of microglial cells by neuroscientists from all backgrounds.

Regarding the terminology used in this chapter, I should point out that microglial cells in the adult central nervous system can assume at least three clearly identifiable states: (1) resting or ramified microglia, as are present in the normal, nonpathological central nervous system; (2) activated or reactive microglia that are found in pathological states but are nonphagocytic; (3) phagocytic microglia that represent full-fledged brain macrophages. Table 5-1 provides a summary of known microglial characteristics during these states as determined in rat brain. For more detailed descriptions the reader is referred elsewhere (Streit et al., 1988; Morioka et al., 1992a; Chapter 59, this volume).

HISTORICAL PERSPECTIVE

Following early descriptions of neuroglia by Virchow in the mid-nineteenth century, various other contemporary pathologists and psychiatrists, including such famous figures as Nissl and Alzheimer, commented on the possibility that the developing central nervous system was being invaded by cells of non-neuroectodermal origin. Speculation abounded as to the source of these invading cells, but with increasing consistency attention was being focused on the possibility that mesodermally derived cells were the invaders. Ultimately this led to the formulation by Ramón y Cajal (1913) of *el tercer elemento,* the third element of the central nervous system, referring to a group of cells that was morphologically distinct from both first and second elements (neurons and astrocytic neuroglia). Ramón y Cajal's third element, defined strictly in morphological terms, received further distinction into oligodendrocytes and microglia by Rio Hortega, the Spanish neuroanatomist who provided the first systematic investigation on microglial cells (Rio Hortega, 1932). Rio Hortega's detailed cytological observations, as well as his view of the origin of microglia, which gave rise to a controversy that has persisted until the present day, can be found in his original treatise and elsewhere (Theele and Streit, 1993; Chapter 10, this volume). The work of Rio Hortega remains relevant for most aspects of current microglial research.

METHODS FOR STAINING MICROGLIA

Silver Carbonate Method

The first selective stain for microglia was the weak silver carbonate method developed by Rio Hortega (1919). Despite its capriciousness, this method remained the only useful histochemical procedure for at least 50 years (Mori and Leblond, 1969). As with many other histochemical techniques involving metallic silver impregnations, Rio Hortega's weak silver carbonate method for microglia has very specific fixation requirements, which do not, however, guar-

antee reproducible results in every preparation. The results obtained are quite variable in terms of numbers of microglia stained, and vary also with the type of animal species used. For reasons unknown, the method seems to work reliably only in rabbit brain (Penfield and Cone, 1961). While it can be carried to the electron microscopic level (Mori and Leblond, 1969), its usefulness is limited by poor structural preservation and the deposition of metallic precipitates, which obscure much of the cellular detail.

Enzyme Histochemical Methods

Thiamine pyrophosphatase (TPPase) and *nucleoside diphosphatase (NDPase)* are the most reliable and specific enzyme histochemical methods for staining resting microglial cells in a variety of species. These methods, which were developed by Novikoff and Goldfischer (1961), have been used successfully to localize microglia at both light and electron microscopic levels (Murabe and Sano, 1981; Schnitzer, 1989). Thiamine pyrophosphatase activity, originally localized to the Golgi apparatus in a variety of cell types, including neurons (Novikoff and Goldfischer, 1961), was later found to bè associated specifically with the plasma membrane of microglial cells and with blood vessels in the central nervous system (Murabe and Sano, 1981).

Nonspecific esterase is an enzyme commonly used to identify microglia in mixed brain cultures (e.g., Sawada et al., 1990). Nonspecific esterase staining is, however, of little use for detecting resting microglial cells in tissue sections. Actively proliferating, reactive microglial cells in the hypoglossal nucleus after peripheral nerve transection also do not show any staining for this enzyme (Schelper and Adrian, 1980). In contrast, nonspecific esterase can be found in microglia-derived brain macrophages that are prevalent in stab wounds. This supports the view that microglia isolated *in vitro,* which are nonspecific esterase-positive, are in fact microglia that have transformed into brain macrophages as a consequence of having been placed into tissue culture.

Activated and/or phagocytic microglia, *in vitro* as well as *in vivo,* show increased activities for a number of various other enzymes that are absent from resting microglial cells. These include acid phosphatase, 5'-nucleotidase, and oxidoreductase (reviewed by Oehmichen, 1980). More recent studies have also shown presence of nitric oxide synthase, lysosomal proteinases, plasminogen activator, lysozyme, purine nucleoside phosphorylase, and elastase (Castellano et al., 1990; Nakajima et al., 1992; Banati et al., 1993). It is worth noting that many of these enzymes are also found in other glial cells types and are there-

fore not necessarily useful as selective histochemical markers for microglial cells.

Immunohistochemical Detection of Microglia

The microglial plasma membrane is complex, containing a large number of receptor and adhesion molecules, as well as enzymatic activities. This large repertoire of potentially immunogenic surface antigens has facilitated the generation of numerous antibodies that can be used in microglial staining procedures. Interestingly, many of the monoclonal antibodies that are presently in use were not produced with the intention of labeling microglia, but were generated originally through immunization against differentiation antigens found on cells of the immune system, such as macrophages, thymocytes, and lymphocytes. Following initial failures of demonstrating presence of some monocytic and lymphoid antigens on human microglia (Oehmichen et al., 1979), it was found later that a mouse macrophage-specific antigen could be localized on resting microglia with a monoclonal antibody designated F4/80 (Hume et al., 1983; Perry et al., 1985). These investigators also succeeded in showing the presence of Fc and complement receptors on resting mouse microglia using antibodies 2.4G2 and Mac-1, respectively. Similarly, ramified microglia in rat brain can be demonstrated reliably using the OX-42 antibody against the CR3 complement receptor (Graeber et al., 1988a). It is important to note that these receptors are also found on macrophages in nonneural tissues, which underscores the phagocytic potential of microglia, as well as their close relationship to the myelomonocytic cell lineage. Cross-reactivity of the antibodies with microglia and blood monocytes has been interpreted to indicate that microglia are derived from monocytes. However, this interpretation should be considered cautiously, since both microglia and monocytes are fully differentiated cell types, and there is no unequivocal evidence to indicate a direct lineage relationship between the two cell types (see Chapter 10).

Microglia in human brain can be visualized using analogous antibodies against typical macrophage surface receptors (Akiyama and McGeer, 1990). In addition to the expression of Fc and complement receptors, other cell adhesion molecules are expressed constitutively on resting microglia in normal brain. Belonging to the integrin superfamily of adhesion molecules, these include typical lymphocytic antigens, such as lymphocyte function antigen, CD4 antigen, as well as leukocyte common antigen (Perry and Gordon, 1987; Akiyama and McGeer, 1990). Species differences between mouse, rat, and human in the constitutive expression of these molecules on resting microglia have been described, and these are likely due to both antibody specificities, as well as variations in tissue processing techniques. B-lymphocyte antigens are also detectable on human microglial cells using monoclonal antibodies of the LN series, in particular LN-1 and LN-3 (Miles and Chou, 1988; Dickson and Mattiace, 1989; Sasaki et al., 1991). While the LN-1 antibody may label both astrocytes and microglia depending on fixation and tissue processing techniques, antibody LN-3 appears to have an exclusive specificity for microglia in both the normal and pathological human brain (Figures 5-1 to 5-3). Thus, the microglial surface membrane bears molecules that are usually associated with white blood cells. Consistent with this, is also the localization of antigens of the major histocompatibility complex (MHC) on microglia. Until a few years ago it was thought that MHC antigens were entirely absent from brain, thereby supporting the conception of the brain as an immunologically privileged organ. However, it is now well documented that the normal brain does indeed contain MHC antigens, and that the principal cell type expressing MHC antigens is the microglial cell (Craggs and Webster, 1985; Hayes et al., 1987; Streit et al., 1989). The constitutive expression of MHC antigens in normal brain is, however, not limited to microglia, but includes endothelial cells, as well as certain cell types located in the wall of cerebral blood vessels, and there are considerable species differences in the levels of constitutive MHC antigen expression on these various cell types. MHC antigen expression is much increased in the presence of pathology and after systemic administration of gamma interferon (McGeer et al., 1988; Steiniger and van der Meide, 1988; Streit et al., 1988; Chapter 59, this volume).

In addition to known monocytic and lymphoid differentiation antigens, various other and yet to be identified antigens have been detected on the microglial membrane through recently developed monoclonal antibodies (Imamura et al., 1990; Gehrmann and Kreutzberg, 1991). Using Western blot analyses, these studies have demonstrated antigens with molecular weights of 46, 62, 70, 78, 95, and 116 kD, thus emphasizing the multiantigenicity of the microglial surface. Another example of this can be found in the recent study by Flaris et al. (1993), which describes the generation of a large panel of new antimicroglial antibodies. However, despite these efforts, a truly specific antibody for microglia, that is, one that does not cross-react with other macrophages in extracerebral tissues, has not been generated to this date. As a general rule, it can be said that any antibody that binds to ramified (resting) mi-

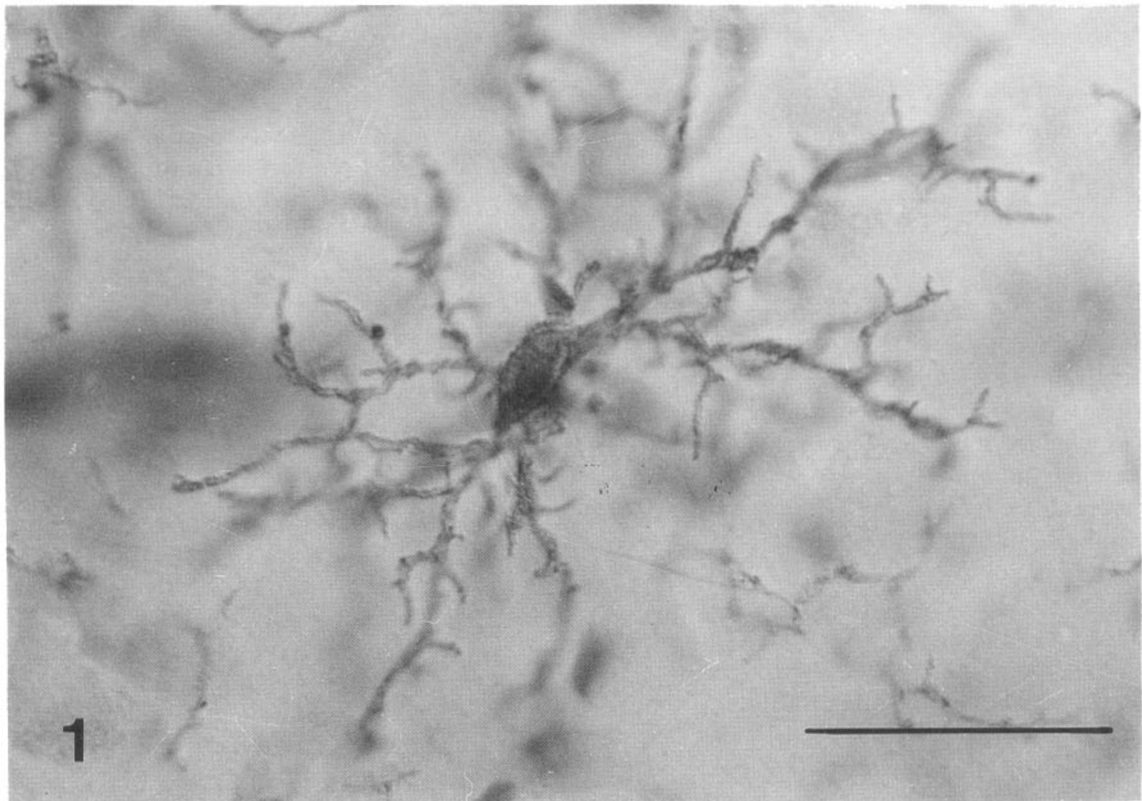

FIG. 5-1. Ramified resting microglial cell in human brain visualized with monoclonal antibody LN-3. Note extensive branching of cytoplasmic processes Bar = 30 μm.

croglial cells will also stain activated microglia and microglia-derived brain macrophages. Conversely, an antibody that stains brain macrophages does not necessarily stain resting microglia. This suggests that either the antigenic repertoire of resting microglia is smaller than that of brain macrophages, or that the level of expression of certain antigens in resting cells is below the detection limit of the immunohistochemical procedure. As an example of this, consider the expression of the intermediate filament protein vimentin. Resting microlia are vimentin-negative, but they quickly upregulate vimentin expression as part of their activation program in response to neuronal injury (Graeber et al., 1988b). Thus, vimentin expression is transient, being evident only in activated microglia and brain macrophages.

Immunohistochemical localization of ramified microglia has been achieved through the use of phosphotyrosine antibodies (Tillotson and Wood, 1989). This procedure detects the products of an enzymatic reaction carried out by tyrosine kinase. There are important functional implications for this observation, since it is known that tyrosine kinases are often associated with cell surface receptors, which are plentiful on the microglial membrane, as discussed above. Various other immunohistochemical methods designed to detect somewhat unconventional antigens, such as vaults and ferritin have also been described (Kaneko et al., 1989; Chugani et al., 1991). Vaults, which are multiarched ribonucleoprotein particles of unknown function, appear to be enriched in microglia during ontogeny, but largely disappear in the adult stage. Ferritin, on the other hand, is a well-known iron-storage protein, and its detection in microglia suggests their active participation in iron metabolism, as in the case of blood monocytes and other tissue macrophages.

In summary, tremendous progress has been made in the last few years with regard to developing immunohistochemical procedures for the detection and identification of microglia. These methods promise to be developed further in the years to come, and they will undoubtedly play a critical role for the continued study of microglial functions.

Lectin Histochemical Detection of Microglia

During the course of investigations examining the distribution of complex carbohydrates in nervous

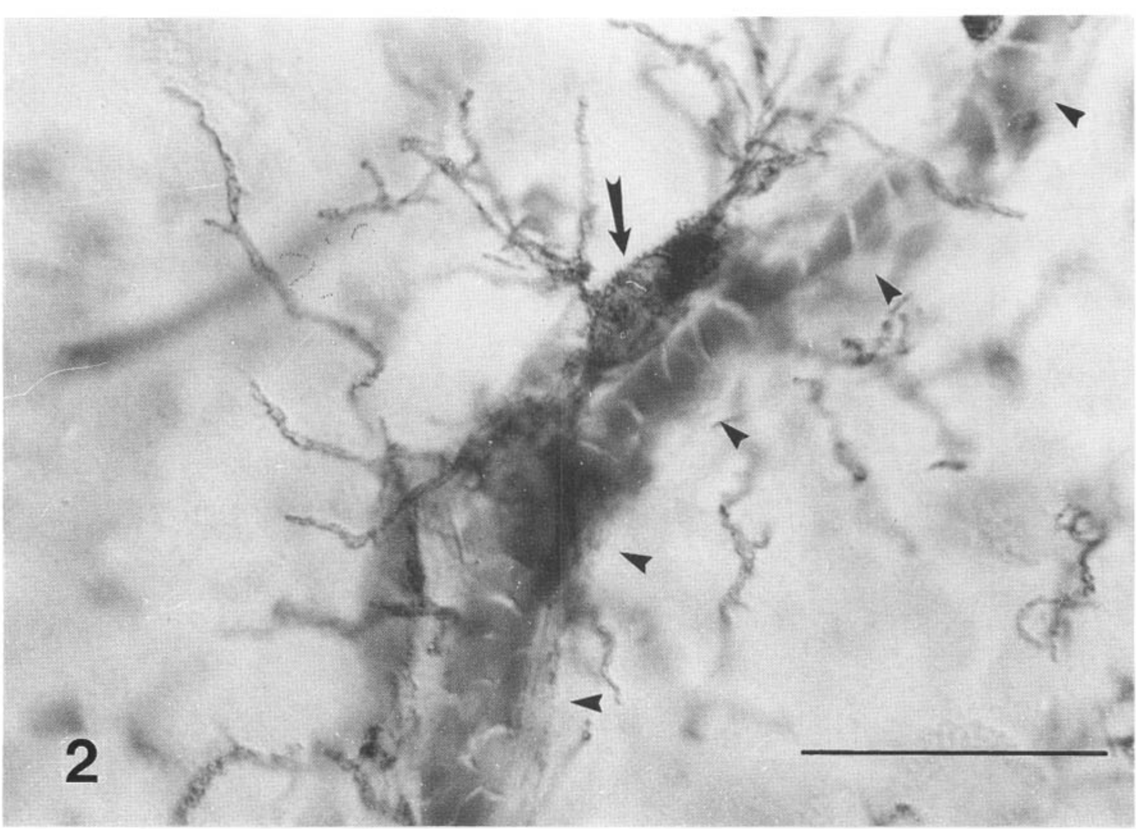

FIG. 5-2. Ramified resting microglial cell in perivascular position (*arrow* points at nucleus). The course of the blood vessel, which is filled with red blood cells, is indicated by the *arrowheads*. LN-3, human brain. Bar=30 μm.

tissue with lectin histochemistry, it was noted that the B_4-isolectin derived from *Griffonia simplicifolia* resulted in the selective visualization of a population of glial cells, which were tentatively identified as microglia (Streit et al., 1985) (see Figure 5-4). These observations were confirmed soon thereafter in human tissue where it was shown that the lectin from *Ricinus communis* could be used as a histochemical marker for microglia (Mannoji et al., 1986). Both lectins have similar sugar binding characteristics in recognizing anomeric forms of galactose: *Griffonia simplicifolia* binds to α-D-galactose and *Ricinus communis* recognizes β-D-galactose residues. Another β-D-galactose-binding lectin derived from mistletoe has been shown to preferentially stain human over rat microglia (Suzuki et al., 1988), stressing the high degree of specificity of lectin binding. Thus, there appears to be only a slight difference in glycocalyx composition between rodent and human microglial cells, being simply one of anomeric configuration. The galactose sugar residues occur as terminal sugars in the oligosaccharide side chains of nervous system glycoproteins, which are embedded in the microglial plasma membrane, as revealed by electron microscopy (Streit and Kreutzberg, 1987). (Figures 5-5 and 5-6). The nature and function of lectin-binding glycoproteins on microglial cells has not yet been resolved. However, it is possible that some of the surface antigens and receptors described in the preceding section might be responsible for lectin binding. In fact, most cell surface receptors show some degree of glycosylation. Lectin staining is perhaps the easiest and most reliable method for visualizing microglia in tissue sections, since the carbohydrate epitopes, unlike most proteins, are relatively resistant to chemical alterations by fixation and tissue processing techniques.

Other Methods for Labeling Microglia

Unlike most cells in the mature central nervous system, microglia are easily induced to proliferate which makes them susceptible to labeling with [^{3}H]thymidine, or any other marker of dividing cells, such as 5-bromo-2′-deoxyuridine. Microglial proliferation is usually triggered by some disturbance in central nervous system homeostasis, such as neuronal injury (Kreutzberg, 1966), but there is also evidence to suggest that microglial proliferation occurs

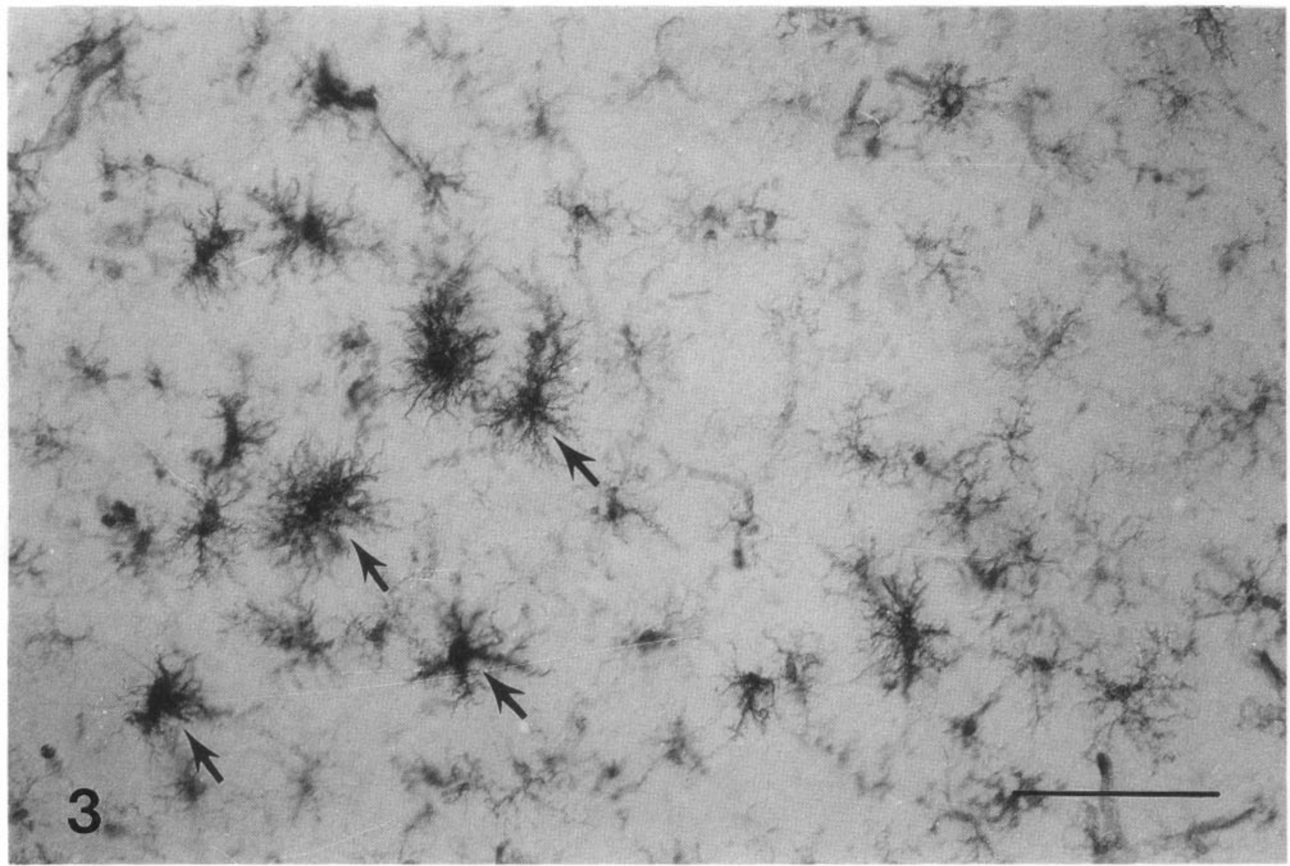

FIG. 5-3. Activated microglial cells in human brain stained with LN-3 (*arrows*). Compared to resting cells, activated microglia show enhanced staining and have a bushy appearance. Bar=100 μm.

normally in the rat brain, albeit at low levels (Korr et al., 1983). Microglia may also be labeled directly or indirectly using various dyes and tracer substances. An example of a direct approach is the intraperitoneal injection of the fluorescent dye, rhodamine isothiocyanate, which results in the labeling of ameboid microglia in the corpus callosum. The rhotamine isothiocyanate-labeled ameboid cells were observed subsequently to transform into rhodamine isothiocyanate-labeled ramified microglial cells (Leong and Ling, 1992), thus confirming earlier observations using colloidal carbon introduced in the form of India ink (Ling et al., 1980). An indirect method for labeling microglia makes use of their ability to phagocytose dead or dying neurons. Following injection of the appropriate tracer substance into nerve axons, the tracer is transported retrogradely toward the parent neuronal cell bodies. If the injected nerve is also axotomized, in many instances this will cause degeneration of the parent neurons, followed by removal of dead neurons through locally present microglial cells which, will phagocytose not only the neuronal debris but also the tracer substance and thus become labeled. Such experiments have been successfully carried out in various systems, including the visual system resulting in the labeling of retinal microglia with the carbocyanine dye DiI (Thanos et al., 1991), the dorsal motor nucleus of the vagus where the neural tracer Fluoro-Gold was used (Rinaman et al., 1991), and also in the rat facial nucleus where Fluoro-Gold was used in conjunction with toxic ricin to induce motor neuron degeneration (Streit and Graeber, 1993).

MICROGLIA AND RELATED CELL TYPES

Definitions

Microglial cells, because they can change their morphology and appearance in certain pathological and developmental states, have been given various descriptive names and attributes, such as *rod cells, gitter cells, globoid and ameboid cells,* to name a few. Even though these terms accurately reflect the cells' changed appearance, the constantly changing terminology has somewhat obscured the true identity of the cells associated with the term microglia. In the

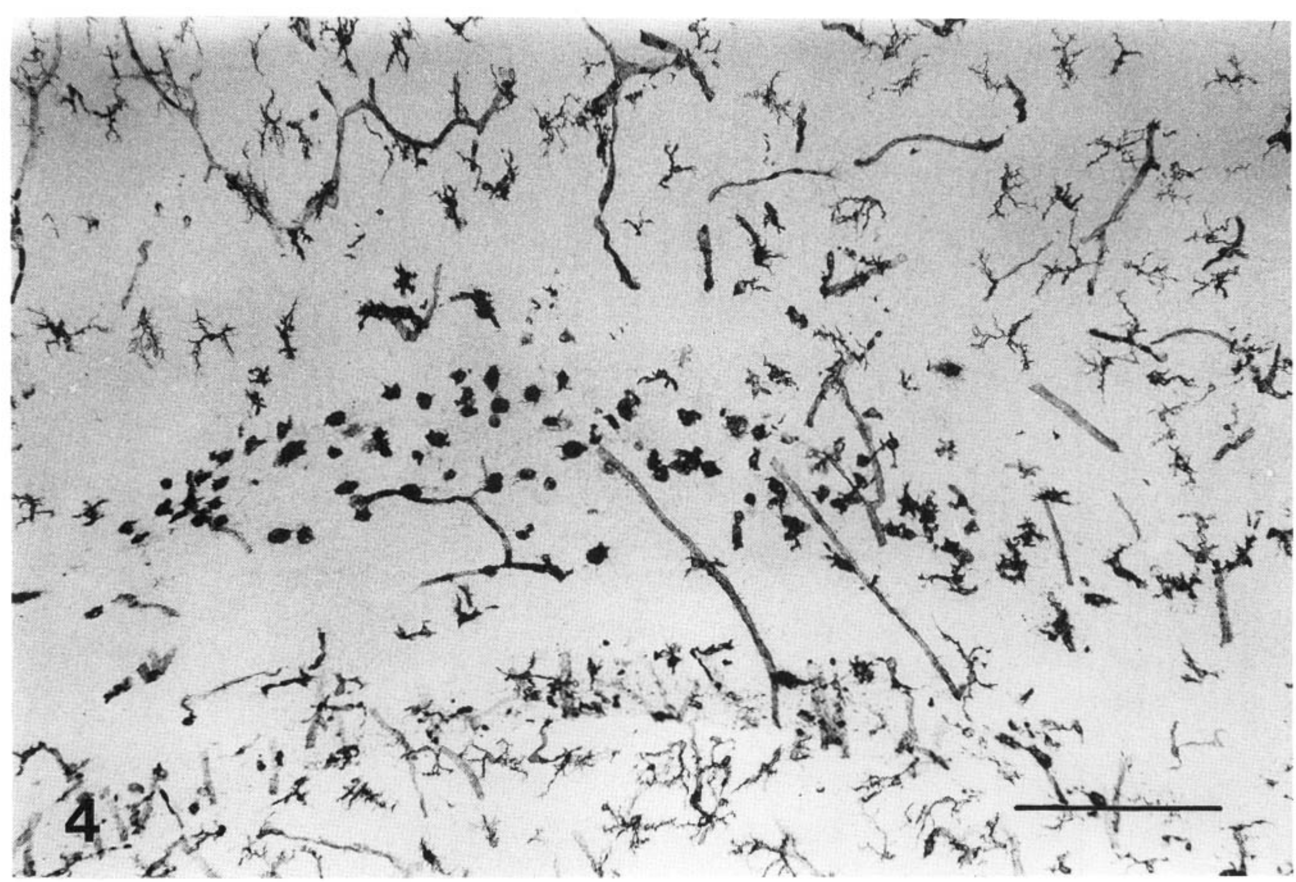

FIG. 5-4. A cluster of round ameboid microglial cells in the supraventricular corpus callosum of the developing rat brain is shown on postnatal day 7 (*center*). Note that increasingly differentiated (ramified) microglial cells surround the central cluster of ameboid cells. Microglia are visualized using the B_4-isolectin from *Griffonia simplicifolia*. Bar=200 μm.

normal and nonpathological brain, resting microglia can be defined both in terms of morphology and phenotype. They are highly branched (ramified) glial cells with a small amount of perinuclear cytoplasm and a small, dense, and heterochromatic nucleus (Figure 5-1). They can be distinguished easily from other glial cells by their surface immunophenotype, that is, they are the only glial cell type which constitutively expresses the CR3 complement receptor (recognized by monoclonal antibody OX-42 in the rat) and binds lectins with a specificity for galactose residues. Furthermore, at the ultrastructural level microglia are recognizable as true parenchymal constituents of the central nervous system, that is, they are located outside of the vascular basement membrane. At the same time, they may be considered part of the perivascular glia limitans, since microglial cytoplasmic processes are found intermingled with the layer of astrocytic foot processes (Lassmann et al., 1991). The observation that microglia are frequently found in the vicinity of blood vessels has resulted in the use of the term *perivascular microglia,* which is yet another descriptive term referring to parenchymal microglial cells, as defined above, which happen to be located near a cerebral blood vessel (Figure 5-2). "Perivascular" microglia are not to be confused with the so-called *perivascular cells,* which, unlike microglia, are *not* part of the central nervous system parenchyma, since they are enclosed by a perivascular basement membrane. Thus, perivascular cells are cellular components of the vascular wall which fit the morphological definition of pericytes (Peters et al., 1991; Mato et al., 1986; Graeber and Streit, 1990a). However, like microglia, perivascular cells are phagocytic and may express MHC antigens (Mato et al., 1986; Streit et al., 1989), which has made it difficult in certain pathological situations to distinguish between perivascular cells and "perivascular" microglia. In the normal brain these two cell types are readily distinguished by their morphology and surface immunophenotype. Perivascular cells are seen only in association with blood vessels, they are not ramified, but rather of an elongate shape, and they can

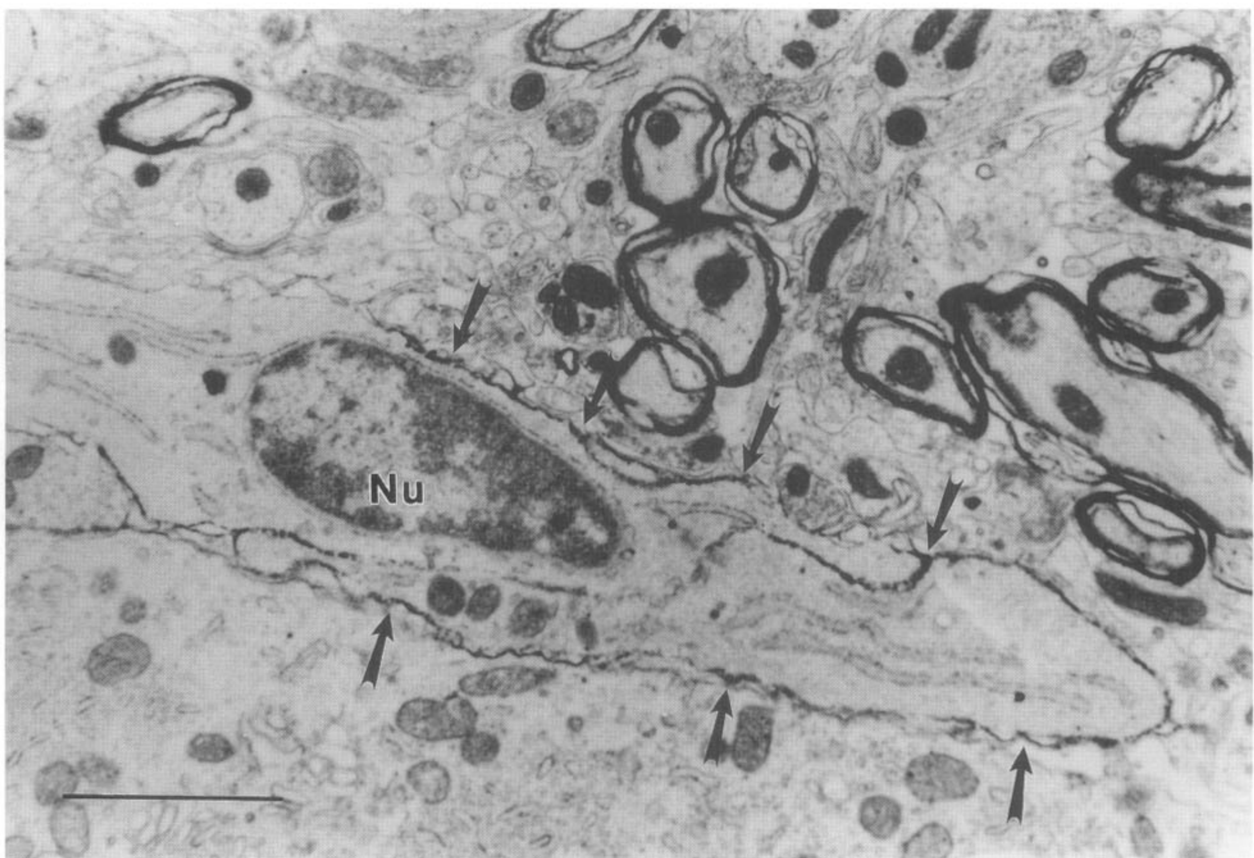

FIG. 5-5. Ultrastructural appearance of a microglial cell in rat brain. The cell has a small heterochromatic nucleus (*Nu*). Its plasma membrane (*arrows*) is accentuated by staining with the *Griffonia simplicifolia* B_4 isolectin, which binds to carbohydrate side chains of membrane glycoproteins. The cytoplasm contains prominent cisternae of rough endoplasmic reticulum. Bar=2 μm. From Streit and Kreutzberg (1987) with permission.

be specifically labeled in the rat with an antibody designated as ED2 (Graeber et al., 1989a). Thus, at least two clearly definable and indigenous sources of brain macrophages are present in normal brain: microglia and perivascular cells. *Brain macrophage* is a general term that encompasses all phagocytic cells, including blood-derived monocytes, which may enter the central nervous system following a lesion that causes a disruption of the blood-brain barrier.

Distribution, Morphology, and Phenotype

Microglia are distributed throughout the normal central nervous system with regional differences having been reported in mouse brain (Lawson et al., 1990). According to these authors, the highest microglial densities are encountered in the hippocampal formation, the olfactory telencephalon, portions of the basal ganglia, and the substantia nigra. A total number of 3.5×10^6 microglia is estimated to reside in the adult mouse brain (Lawson et al., 1990). Individual microglial cells typically occupy distinct territories, such that cytoplasmic processes of neighboring cells do not make contact with each other. The morphology and branching patterns of microglial cells show heterogeneity between different brain regions, and this is perhaps most remarkable when comparing cells in gray and white matter. Microglia in gray matter tend to be profusely ramified with processes extending into all directions, while cells in the white matter often align their cytoplasmic extensions in parallel, but also at right angles, to nerve fiber bundles. Thus, the shape of microglial cells adapts well to the architecture of the brain region they populate. Microglial phenotype, in contrast, appears to be influenced by the chemical composition of the microenvironment. For example, MHC class II-positive, as well as CD4-positive microglia are localized preferentially in white matter of normal brain (Hayes et al., 1987; Perry and Gordon, 1987; Streit et al., 1989; Mattiace et al., 1990). Brain regions lacking a blood-brain barrier, such as the cir-

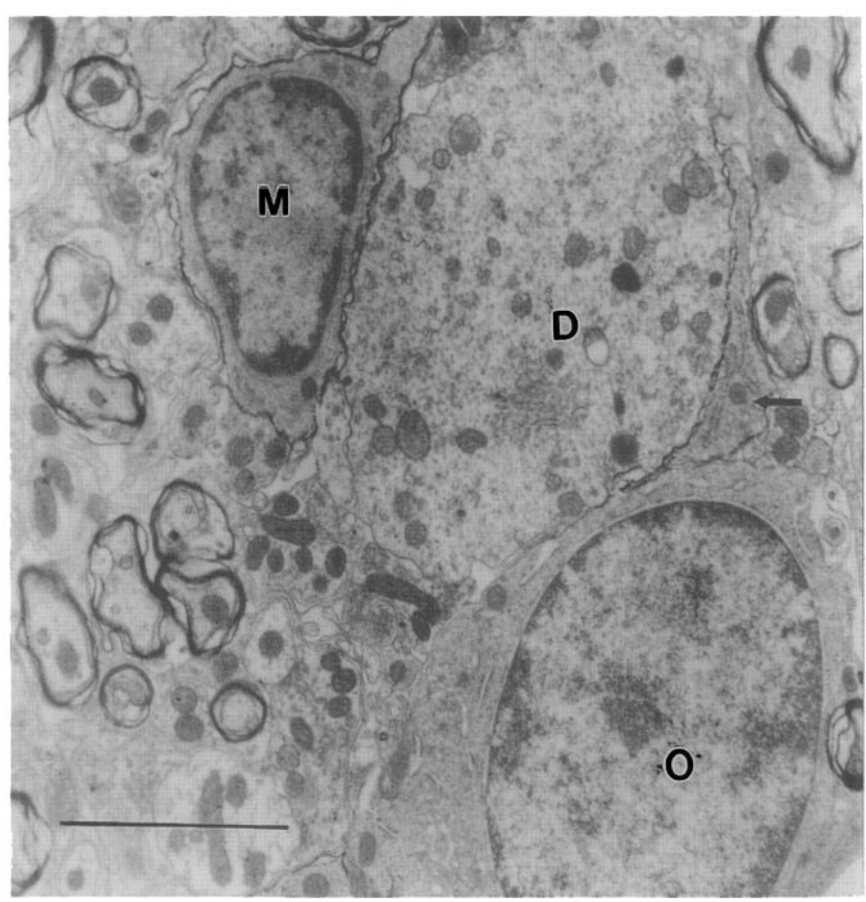

FIG. 5-6. The electron micrograph shows a microglial cell (*M*), an oligodendrocyte (O), and a large dendrite (*D*). Both cell types have a heterochromatic nucleus which is larger in the oligodendrocyte. Note lectin staining of the microglial plasma membrane (as in Figure 5-5). A cell process of the microglial cell is wrapped around the dendrite and appears on the other side (*arrow*). Bar=2 μm. From Streit and Kreutzberg (1987), with permission.

cumventricular organs, do show microglia and microglia-like cells, such as the Kolmer cells of the choroid plexus, with a different phenotype, suggesting that serum proteins influence microglial phenotype (Perry et al., 1992). This is supported further by *in vivo* studies showing profound changes in microglial phenotype after brain lesions that compromise the blood-brain barrier, such as forebrain ischemia and kainic acid injections (Morioka et al., 1992b; Finsen et al., 1993). Similar changes in microglial immunophenotype occur also when the cells are maintained *in vitro* using serum-containing culture medium (Graeber et al., 1989b).

Microglia in Tissue Culture

Although the maintenance of microglia-brain macrophages in tissue culture is a technique that was already in use during the early 1900s, and possibly even earlier, the *in vitro* approach has regained significant popularity during the 1980s. The technique described by Giulian and Baker (1986) is now widely used with numerous modifications. When culturing microglial cells, perhaps more so than with any other neural cell type, it becomes immediately apparent that microglia *in vitro* are very much different from microglia *in vivo,* and that they closely resemble cultured macrophages. The preparation of primary mixed brain cultures, from which microglia are isolated, causes the generation of huge amounts of tissue debris. This, together with a required high serum content of the growth media promotes more or less instantaneous transformation of microglial cells into microglia-derived brain macrophages. Although it has been reported that prolonged maintenance of isolated microglia in lipopolysaccharide-free media (Gebicke-Haerter et al., 1989) can result in the formation of branched cells *in vitro,* the extensive ramification of microglial processes as it is seen in tissue sections is rarely achieved in the culture dish.

However, and despite these difficulties, tissue culture studies of microglia during recent years have contributed substantially to our current understanding of microglial biology. The most significant contribution that has come from the *in vitro* experiments is the demonstration that microglia secrete a number of cytokines, such as interleukin 1 (Giulian et al., 1986), interleukin 6 (Frei et al., 1989), and tumor necrosis factor (Sawada et al., 1989). Tissue

culture studies have additionally revealed microglial responsivenes to growth factors, such as GM-CSF and CSF-1, which are potent inducers of microglial proliferation (Giulian and Ingeman, 1988; Suzumura et al., 1990). Microglial secretion of, and their responsiveness to, cytokines-growth factors is currently under intense investigation, and it can be anticipated that future studies will reveal additional cytokines-growth factors involved in mediating microglial functions. The demonstration that microglia are highly secretory cells has provided a conceptional complement to the *in vivo* studies that have focused on immunophenotypic plasticity of surface molecules. Thus, *in vitro* and *in vivo* approaches have uncovered secretory and surface-bound molecules, respectively, both of which are necessary to facilitate microglial functions. The two experimental approaches have converged into a concept that now views microglia as the local immune system of the brain (Graeber and Streit, 1990b).

Microglia in Different Species

While microglia are best studied in rodents and human, primates and most other mammalian species are known to have microglia. Since species-specific antibodies for localizing microglia in cat, dogs, and primates are not yet available, the aforementioned enzyme and lectin histochemical methods are likely to be feasible alternatives. Recently, we have been able to stain microglial cells in the brain of the Florida manatee using the B_4-isolectin from *Griffonia simplicifolia*. The fact that the same lectin can also be used for staining microglial cells in an invertebrate species, namely, the leech (McGlade-McCulloh et al., 1989), strongly suggests that the glycoconjugates recognized by the lectin represent evolutionary conserved molecules. Similarly, NDPase histochemistry has been used for visualizing microglia in nonmammalian species, such as chicken and lizard (Fujimoto et al., 1987; Castellano et al., 1991). A recent report describes immunohistochemical staining of microglia in *Oreochromine* fish, using a new monoclonal antibody directed against fish macrophages (Dowding et al., 1991). The study also suggests that fish microglia, just like their mammalian counterparts, are capable of proliferating after nerve injury.

MICROGLIAL FUNCTIONS AND FUNCTIONAL PLASTICITY

The term functional plasticity was introduced to emphasize the enormous malleability of microglial cell shape and immunophenotype seen under pathological conditions (Streit et al., 1988). While specific aspects of microglial activation in pathological circumstances are discussed in Chapter 59 of this book, I should like to note, in a general sense, that following a pathological insult microglial cells tend to become hypertrophied with stout processes and may take on a bushy appearance (Figure 5-3). If neuronal degeneration is present, they may continue their metamorphosis and subsequently transform into round brain macrophages.

In the normal brain, such microglial plasticity is encountered during development. Although the origin of ameboid microglia is still a matter of dispute, there is little doubt that, during development, round ameboid cells differentiate to become the highly ramified resting cells seen in the adult. In support of this process is the presence of increasingly ramified microglia in the vicinity of ameboid microglial cell clusters that are prevalent in various white matter regions of the young postnatal rodent brain (Figure 5-4). Thus, structural plasticity of microglia during development and during pathology proceed in opposing directions with cell morphology becoming more ramified during ontogeny, and less ramified during pathology. While this may seem trivial, it nevertheless serves to underscore the direct relationship of cell shape to function, hence the term functional plasticity. We already know that these morphological transformations are accompanied by substantial changes in cell phenotype, and it is virtually certain that they are also accompanied by changes in cytokine production and secretion. However, the latter are still subject to ongoing investigations. Thus, we hope to soon be able to define functional plasticity in terms of both membrane-associated, as well as secretory activity. As to well-defined microglial functions in the adult, these are for the most part related to microglial activity in the diseased brain and include antigen presentation, cytotoxicity, neovascularization, and phagocytosis. Some of these functions are also important for the developing brain, in particular, phagocytosis of dying neurons. For example, naturally occurring cell death is prominent in the developing retina, and dying retinal ganglion neurons are removed by microglial cells (Hume et al., 1983). Although it has been suggested that retinal ganglion cell death serves to attract bloodborne macrophages to populate the retina and differentiate into microglia, this hypothesis seems incompatible with the fact that microglia are present in the rodent retina several days before the onset of ganglion cell death (Ashwell et al., 1989).

In the normal adult brain, microglial functions are still ill-defined; however, it would be safe at this time to propose that microglia serve a major role in the

immune surveillance of the central nervous system. Their ubiquity and regular spacing throughout the brain and spinal cord, as well as their morphology and phenotype, strongly indicate their function to be one of specialized immunocompetent cells guarding one of our most vital and vulnerable organs.

6 Morphology of nonmammalian glial cells: functional implications

N. JOAN ABBOTT

HISTORICAL PERSPECTIVE

Insights from Studies of Nonmammalian Glial Cells

This volume considers the neuroglial cells of many animal groups. The desire to understand the functions of the human brain and its pathologies has meant that much work has been done on mammalian preparations. However, studies on nonmammalian glial cells can give information not available from the study of mammalian glia alone. This chapter summarizes the morphology of nonmammalian glial cells, concentrating on examples where the structural information contributes to understanding of function. Certain animal groups, such as insects, fish, amphibia, and birds, are particularly convenient for the study of glia during development because of the transparency or accessibility of the embryo. The large glial cells of certain invertebrates and lower vertebrates have proved particularly convenient for biochemical and electrophysiological study. By surveying glial morphology and function in a range of animal groups it is possible to present a picture of the evolutionary pressures that have shaped the arrangements seen in higher forms. Studies of the morphology of neuroglia thus give insights into the embryology, physiology, and evolution of neuroglial cells.

Definition and Classification of Nonmammalian Glia

Although the first anatomical studies of glia by Virchow, Golgi, and Ramón y Cajal between 1856 and 1920 used mammalian material, a comparative approach was being applied even during this period. The first tentative identifications were based on histological appearance and resemblance to mammalian glia. Thus in the cephalopod optic lobe, Lenhossèk (1896) described "bushy glial cells," and Ramón y Cajal (1917) described "epithelial cells" around neurons and "protoplasmic astrocytes" throughout the lobe. The leech (annelid) was of major medicinal interest, and its glia were described by several eminent histologists, including Rio Hortega and Retzius (see Ito, 1936).

There are two chief problems in describing nonmammalian glia: first, the definition of what constitutes a "glial cell", and second, the classification of glial subtypes. Some authors used the term "glia" for all cells within the boundary of the nervous system that were not clearly neuronal (Clayton, 1932; Hess, 1958). However, this classification frequently included cells derived from blood vessels, connective tissue, and mesenchymal elements. Radojcic and Pentreath (1979) proposed that the term "glia" should be restricted to nonneuronal cells (1) originating from embryonic ectoderm, and (2) having an intimate morphological relationship with neurons (sheathing, investing), or separating the neuronal compartment from mesodermal elements (e.g., at the vascular interface). It is not always possible to apply these criteria rigorously, since it can be difficult to distinguish glia from neurons, and embryonic information is often lacking, but they will form a working basis for the present account.

Invertebrate glia show a variety of morphologies depending on species and location. Glial cells appear to be absent in the lowest groups, the Mesozoa, Porifera, Coelenterata, and Echinodermata, but present in Platyhelmintha, Aschelmintha, Annelida, Arthropoda, and Mollusca (reviewed by Radojcic and Pentreath, 1979) (Figure 6-1). As invertebrates do not have true compact myelin, although some show periaxonal glial wrappings (Kirschner and Blaurock, 1992), no class of cell equivalent to oligodendrocytes can be identified. Moreover, immunocytochemical markers for astrocytes fail to cross-react with invertebrates in most cases, so it has not been possible to define a class of invertebrate glial cell equivalent to vertebrate astrocytes. Instead, invertebrate glia have been described according to their position (e.g., *sheathing, perineuronal, neuropilar, gliovascular*) or morphology (*plasmatic, protoplasmic, fibrous, Schwann-like*) (Radojcic and Pentreath, 1979). Of

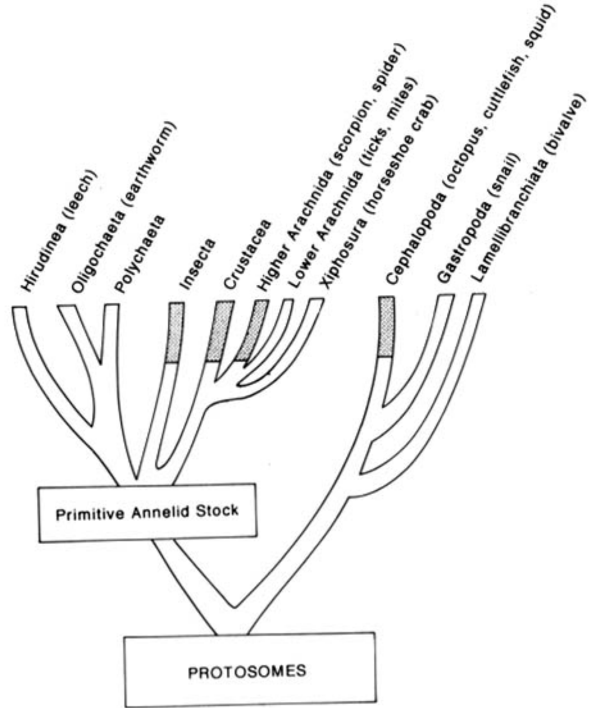

FIG. 6-1. Evolutionary tree of higher invertebrates, with modern groups at the top. Groups with a glial blood-brain barrier are shown (*shaded*). [Basic tree after Walker and James (1980).]

the commonest forms, *protoplasmic glia* have short thick processes, while *fibrous glia* have long thin ones; both may contain intermediate filaments.

Advantages of Nonmammalian Glia as Experimental Preparations

The modern interest in glial cell physiology began in the early 1960s (reviewed in Nicholls et al., 1992). The glial cells of invertebrates and lower vertebrates have some advantages for physiological study, chiefly their size and accessibility. Examples are the giant glia of the leech abdominal ganglia suitable for studies of electrophysiology and metabolism, the glial *perineurium* forming the insect blood-brain barrier, and the Schwann cells of the cephalopod peripheral nerve. Where comparison between invertebrate and vertebrate glia has been possible, several common properties have emerged, showing that studies in a range of animal groups can add to our understanding of glial architecture and function.

Structure and Classification of Glial Cells in Relation to Function

The earliest histologists were content to describe the position of glial cells and to categorize them on morphological criteria. As physiological and pharmacological studies progressed, it became obvious that the function of glial cells was closely related to their morphology. Thus glia associated with vertebrate neurons develop specific associations with axons (oligodendrocytes and Schwann cells forming internodal membrane wrappings, astrocytes sending processes to the nodal regions) and dendrites (enclosing groups of synapses in "glomeruli"), and glial cells at the blood-brain interface either form a sheath of endfeet on the vessel wall (most higher vertebrates) or themselves form an epithelium-like barrier (elasmobranchs and higher invertebrates). The elongated processes of glial cells in the retina and the syncytial nature of the glial network in vertebrate brain may play important roles in spatial redistribution of potassium (see Chapter 37). Any classification that does not consider function is likely to be unsatisfactory. This chapter reviews the morphology of nonmammalian glial cells, highlighting features that contribute to glial physiology and, where possible, giving a classification that incorporates functional information.

INVERTEBRATE GLIAL CELLS

Organization of Invertebrate Nervous Systems

Metameric invertebrates (including annelids, insects, and Crustacea) have a segmental body plan, reflected in the organization of the central nervous system as a series of segmental neural ganglia, linked by axons running in "connectives," with some fusion of ganglia in regions such as the head and thorax (Bullock and Horridge, 1965). In mollusks, most ganglia are in the region of the head, with a few outliers in the tissues. Most invertebrate ganglia do not have an internal vasculature, although intraganglionic vessels are found in higher annelids, Crustacea and cephalopod mollusks. Invertebrate glial morphologies reflect this diversity of organizational pattern.

Annelids

The Large Glia of the Leech Central Nervous System Surround Groups of Neurons. The importance of the leech in medicine made it an obvious choice for studies on the anatomy and embryology of the nervous system, and the leech segmental ganglia were described in detail by histologists Ramón y Cajal, Rio Hortega, and Retzius (reviewed in Muller et al., 1981), and more recently with the electron microscope (E. Gray and Guillery, 1963; Coggeshall and Fawcett,

1964). Each segmental ganglion is less than 1 mm in diameter, contains around 400 neurons, and is quite transparent. The neurons are organized in a stereotyped "map" with distinctive positions, shape, branching patterns, and physiology. A small number of large glial cells (*packet glia, neuropil glia, connective glia*) fill the spaces between the neurons and axons. Groups of neuron cell bodies and their initial axonal processes are embedded within a single large (packet) glial cell (Figure 6-2), while in the connectives many hundreds of axons are surrounded by another large glial cell several millimeters long. Four large ectodermal precursor cells (N, O, P, and Q teleoblasts) are responsible for the production of all the cells of the adult ganglia. As also recently established for vertebrate neural development, the earliest precursors give rise to both neurons and glial cells. Thus the N teleoblast generates the neuropil glial cell as well as the Retzius neuron, a sensory neuron specific for touch and nociception (Kramer and Weisblat, 1985; Ho and Weisblat, 1987). Glial processes are juxtaposed to sites of neurogenesis in the leech germinal plate, suggesting a role in glial guidance of neuronal outgrowth and migration (Cole et al., 1989).

The leech glia have proved ideal for microelectrode studies, and have contributed to our understanding of glial electrophysiology, pH and potassium regulation, and sensitivity to neurotransmitters (see Chapters 11 to 20).

The Annelid Blood-Central Nervous System Interface Is Leaky to Small Ions. The leech ganglia and connectives lie in a blood sinus, separated from the blood by an "endothelium" and basal lamina. Kuffler and Potter (1964) found that (protein-bound) trypan blue was excluded by the endothelium. However, by using the membrane potential of the leech neuron as an indicator of its own local ionic microenvironment, Nicholls and Kuffler (1964) showed that there was relatively rapid exchange between the medium and the neuronal surface (half-time for exchange of potassium and sucrose for sodium < 10 seconds) *in situ*. Together with electron microscopic evidence showing absence of tight junctions in the cell layers lining the blood sinus, these studies showed that the leech ganglion has no surface barrier to small molecules. Kai-Kai and Pentreath (1981) showed that ionic lanthanum has free access to the leech ganglionic interstitium. Studies on the connective gave similar results. Ion substitution and electron microscopic studies in another annelid, the serpulid worm *Mercierella* show that this species also lacks a blood-brain barrier (Skaer et al., 1978); this appears to be the general annelid pattern.

The Extracellular Space, Not Glia, Is the Major Route for Exchange of Materials Within the Nervous System. As the leech glial membrane potential did not change during substitution of sucrose for sodium (Nicholls and Kuffler, 1964), it was concluded that these molecules moved through the extracellular space. This was also the conclusion from studies with radiolabeled sucrose, inulin, and dextran (Nicholls and Wolfe, 1967). These experiments led to the modern view that the extracellular space is the most important medium for exchange of materials within the nervous system (see Chapter 26), and between blood and neurons, although there may be situations where glial cells provide local trophic support to nerve cells (Wolfe and Nicholls, 1967; see also the sections *Lower Mollusks* and *Cephalopod Mollusks* below), or act as a pathway for redistribution of ions (see Chapter 37).

Arthropods

Glial Cells in Insects and Crustacea Are Classified by Morphology and Location. There are sufficient homologies of structure and function among arthropods (Xiphosurans such as the horseshoe crab *Limulus,* arachnids such as spiders and scorpions, Crustacea, and insects) to regard them as closely related animal groups (Figure 6-1), although details of their evolutionary relationships are not fully understood (Barnes, 1980).

The nervous systems of insects and Crustacea have been the subject of intense morphological and physiological study, and several attempts at glial classification have been made. Strausfeld (1976) illustrates a range of insect glial morphologies from studies since Ramón y Cajal's early work (Figure 6-3). The most coherent descriptions come from detailed examination of individual species, in which physiological and anatomical studies have been done in parallel [e.g., insects: cockroach (*Periplaneta*), fly (*Musca*), bloodsucking bug (*Rhodnius*), fruit fly (*Drosophila*), stick insect (*Carausius*); Crustacea: crab (*Carcinus*), crayfish (*Procambarus*)].

This is a generalized summary, based on insects and higher Crustacea. An outer layer of glial cells, the *perineurium* forms a complete sheath around ganglia and interganglionic "connectives" (Figure 6-4) and, to a variable extent, around peripheral nerves (Lane, 1974; Lane and Abbott, 1975; Treherne and Schofield, 1981). Small neurons and axons are surrounded by glial processes, either singly or in bundles. Giant axons are enveloped in a multilayered wrapping formed by multiple turns of *mesaxonal* glia. Gap junctions between the insect perineurium and the underlying glia give rise to cell-cell

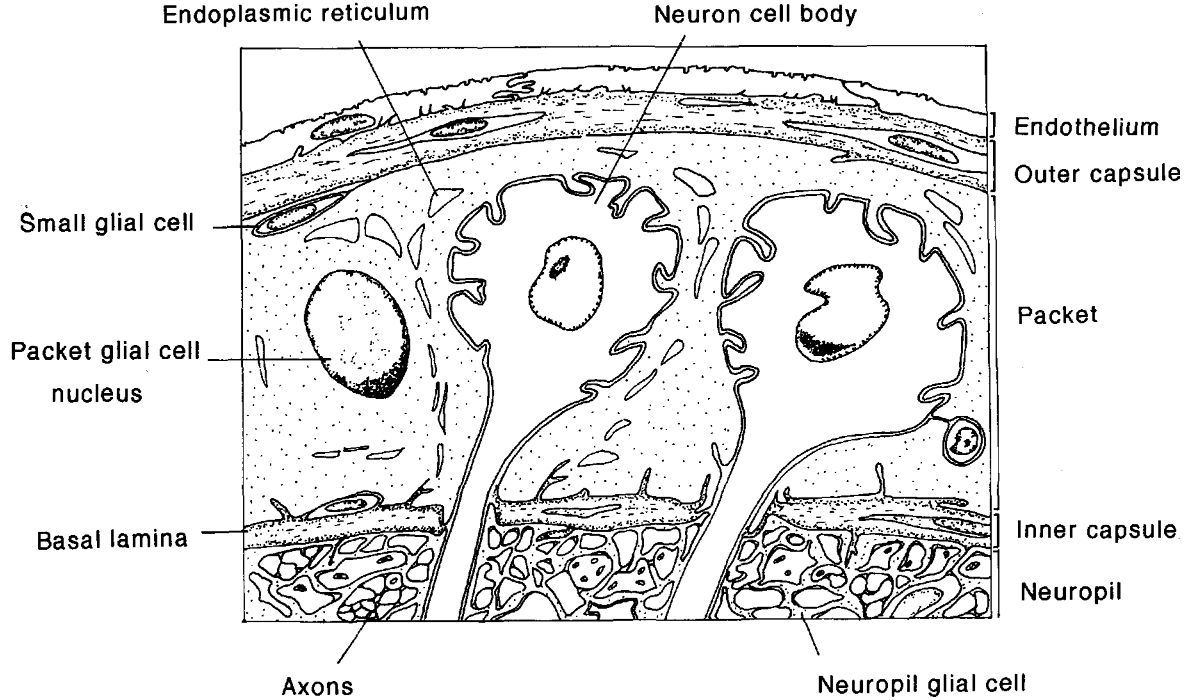

FIG. 6-2. The three main types of glial cell in the leech ganglion (Hirudinea, Annelida): *1*, Small glial cells under the outer capsule sheath, 2, packet glial cell surrounding neuron somata, and 3, neuropil glial cell around small axons. Both the endothelium and glial layers are permeable to small ions. [From Coggeshall and Fawcett (1964), with permission.]

electrical coupling. Insect perineurial cells are metabolically active (Wigglesworth, 1960) and show many morphological features of transporting epithelia (Maddrell and Treherne, 1967), including high mitochondrial density, elaboration of junctional complexes, presence of fat globules, and clusters of glycogen granules. The glial cells surrounding large neuron cell bodies send "trophospongial" processes into the perikarya and axon hillock regions (reviewed in Lane, 1981; Sandeman and Luff, 1973). The long cellular processes of insect glial cells may contain dense arrays of microtubules (Lane, 1974). In some insects, parts of the interstitial space between the glial cells are expanded into *lacunae* (the *glial lacunar system*) filled with dense extracellular material containing anionic substances such as hyaluronic acid and glycoproteins that may act as an ion reservoir (Treherne et al., 1982).

More detailed numerical classification of glial subtypes (type-1, type-2, etc.) has been attempted for *Rhodnius* and *Periplaneta* (Wigglesworth, 1959, 1960), and *Musca* (Sohal et al., 1972; Strausfeld, 1976), but these classifications are based on somewhat arbitrary morphological criteria (position, relation to neurons), and become confusing in any comparative account because the numbering systems do not correspond. A numerical classification is avoided here.

The main difference between insects and decapod Crustacea (crayfish, crab, lobster) is that the crustacean groups have a system of vascular channels running within the nervous system (Abbott, 1971a, 1971b) (Figure 6-5). Invaginations of the perineurium form the layer of perivascular glia lining the blood channels.

Glia of the Insect Embryo Act as Guideposts in Development. The insect embryo has several functionally distinct classes of glia, some with important roles in development (Jacobs and Goodman, 1989; Jacobs et al., 1989). Ablation of one particular glial cell in the grasshopper, the segment boundary cell, causes disturbance of neuronal growth cone guidance in development (Bastiani and Goodman, 1986). In *Drosophila,* two pairs of midline glia, the MGA and MGM cells, are important in the formation and separation of commissural axon tracts across the midline, as shown by abnormalities of the commissures in mutants involving these glia (Klämbt and Goodman, 1991).

Glial Cells of the Arthropod Perineurium Contribute to the Blood-Brain Barrier. Insects, higher arachnids, and decapod Crustacea, possess a blood-brain barrier (reviewed in Abbott et al., 1986b). It has been proposed that a blood-brain barrier is necessary

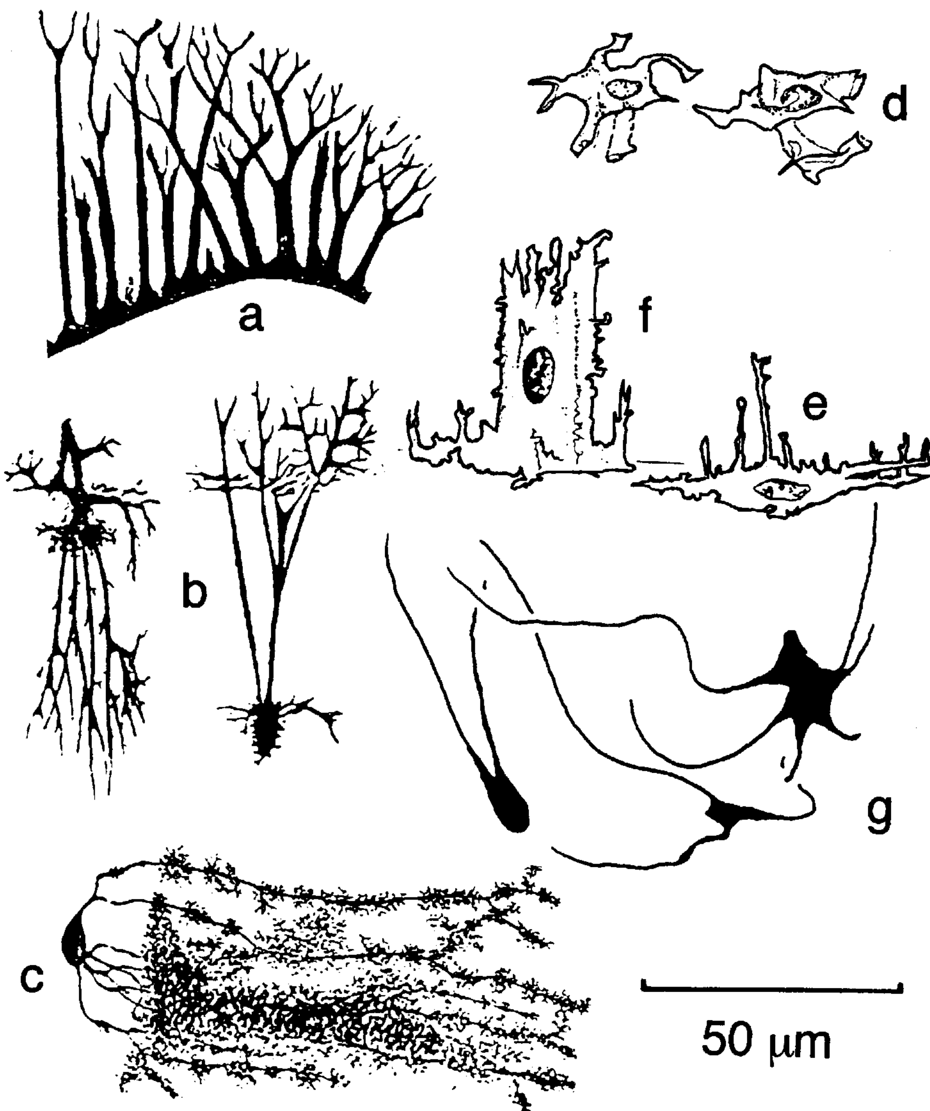

FIG. 6-3. Forms of insect neuroglia. [From Strausfeld (1976), with permission.] (A) Epithelial cells. (B) Displaced epithelial cells. (C) Radiate glial cells. where the nervous system is involved in complex sensory and motor processing because of the need for ionic homeostasis around central integrating synapses (Abbott et al., 1986a). Some insects have additional requirements for an effective barrier, since their blood (hemolymph) may contain unusually high or fluctuating levels of potassium (Lettau et al., 1977).

Unlike the situation in higher vertebrates, where the blood-brain barrier is formed by endothelial cells lining cerebral microvessels, the barrier in insects and Crustacea is formed by glial cells. In insects the barrier resides in the innermost zone of the perineurium, or "bracelet cell" layer (Treherne and Pichon, 1972; Lane, 1991). Extracellular tracers such as horseradish peroxidase, microperoxidase, and lanthanum fail to penetrate into the interstitial space around neurons. The barrier has been attributed to tight junctions in the perineurium (Lane, 1991), but these have not been seen in all insects; septate junctions (Juang and Carlson, 1992) or extracellular material in narrow interstitial clefts may contribute to the restriction in some cases.

The perineurial barrier is relatively tight to small ions (reviewed in Treherne and Schofield, 1981; Schofield and Treherne, 1984, Schofield et al., 1984), and may be under hormonal modulation, as the stress hormone octopamine causes a decrease in potassium permeability (Schofield and Treherne, 1986). This suggests that in periods of stress, the brain would be more protected from fluctuations in plasma composition and hence better able to produce coordinated neural activity. No equivalent tightening mechanisms have been described for the vertebrate endothelial barrier.

The situation in insect peripheral nerves is variable; large nerves generally have a perineurial barrier, but in small nerves and nerve terminals the bar-

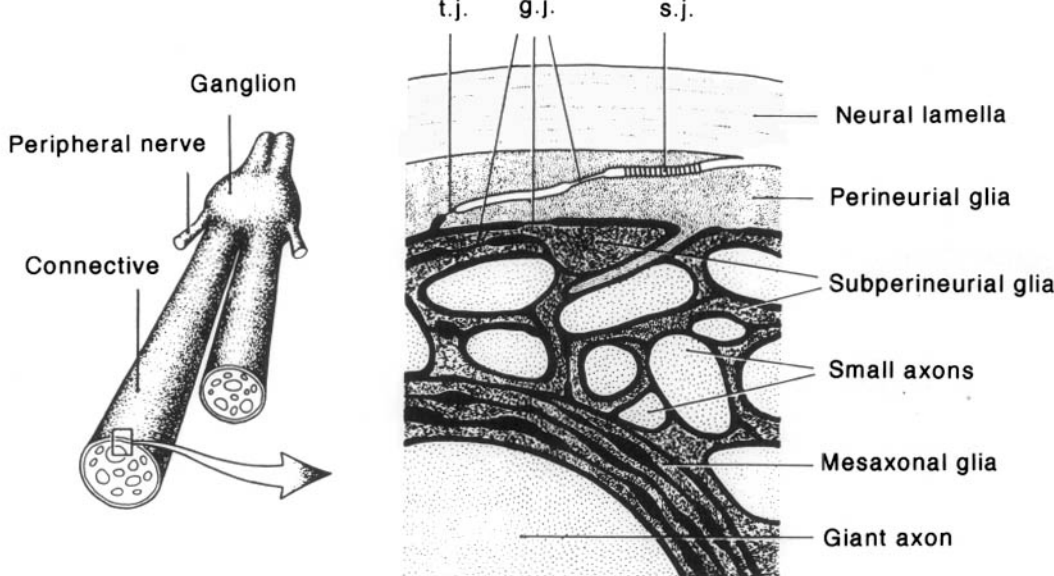

FIG. 6-4. Outer layers of the cockroach *Periplaneta* (Insecta) central nervous system connective, to show the three main types of glia: perineurial, subperineurial, and mesaxonal. The tight junctions (*t.j.*) of the perineurium form a diffusion barrier at the blood-nervous tissue interface. Gap junctions (*g.j.*) and septate junctions (*s.j.*) are also present. [From Treherne and Schofield (1982), with permission.]

rier may be leaky to extracellular tracers (Lane, 1991). Neurosecretory zones have a permeable interface between the nerve terminals and the blood (Lane et al., 1975).

In decapod Crustacea the barrier is formed by the glial perineurium surrounding the ganglia, and by its invaginations the perivascular glia, relatively tight to ionic lanthanum (Lane et al., 1977). Freeze fracture information is lacking, but thin sections show occasional tight junctions (Lane and Abbott, 1975). Electrophysiological studies show that the crustacean perineurium is leakier to potassium than that

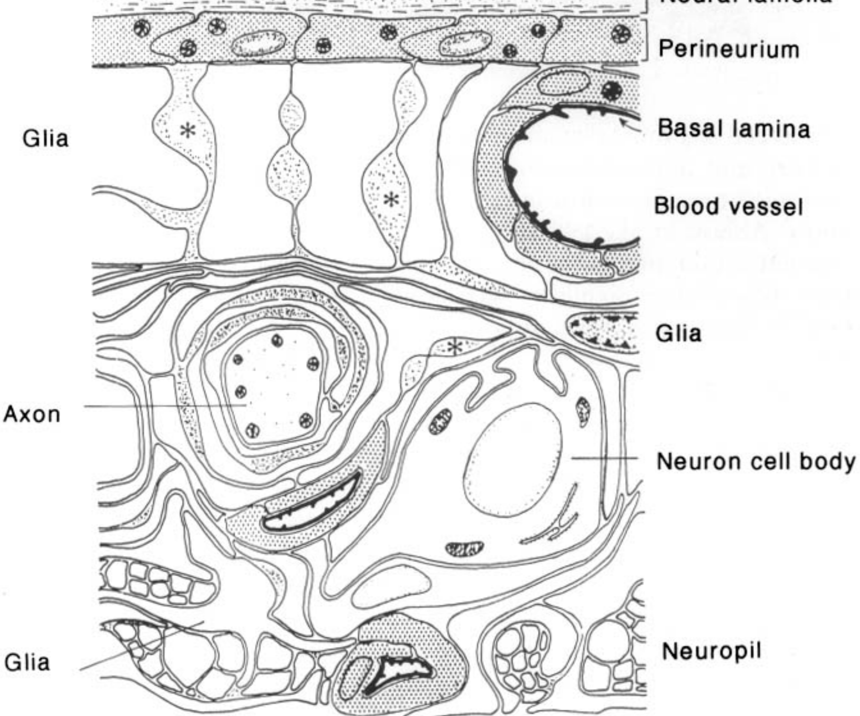

FIG. 6-5. Glial cells of the cerebral ganglion of the shore crab *Carcinus* (Crustacea). Extensions of the glial perineurium (shaded) form perivascular cuffs. Other glia with distinct morphologies can be seen under the perineurium (*subperineurial*), surrounding the cell body zone (*sheathing*), winding around axons (*mesaxonal*), enclosing neuronal somata, with trophospongial invaginations (*perineuronal*), and surrounding bundles of small axons in the neuropil (*neuropilar*). The perineurial and perivascular glia form the blood-brain barrier. [From Abbott (1971a), with permission.]

of insects (Abbott and Pichon, 1987; Butt, 1991). Electron microscopic studies show that the peripheral nerves of decapod Crustacea have a relatively thin and incomplete perineurium, and electrophysiological studies confirm that the peripheral nerve sheath in crab and crayfish is relatively leaky to ions (Abbott et al., 1975; Abbott and Pichon, 1987). In lobster nerve roots, the giant axons are somewhat more protected; here the blood-nerve barrier appears to be a combination of incomplete tight junctional zones, a tortuous diffusion pathway produced by the multilamellar glial ensheathment, and diffusional restriction caused by extracellular material in the cleft (Villegas and Sanchez, 1991).

The relatively open blood-nerve barrier in Crustacea compared with insects may reflect the fact that crustacean blood is a more suitable (and stable) ionic medium for neuronal function than insect blood. The retention of a barrier around ganglia, connectives and giant axons may reflect the need for better ionic homeostasis around integrating synapses and axons involved in survival behaviour such as fast escape responses and prey catching.

Glia at the Arthropod Neuromuscular Junction Are Specialized for Transmitter Uptake. Glial cells are closely apposed to the nerve terminals at the neuromuscular junction of both excitatory (glutamatergic) and inhibitory (GABAergic) nerves in arthropods. Autoradiographic evidence shows that here glial cells are the predominant site of transmitter uptake, an important step in transmitter inactivation and recycling (Faeder and Salpeter, 1970; Orkand and Kravitz, 1971; Evans, 1974; Horwitz and Orkand, 1980; see Chapter 15, this volume).

Arthropod Glial Anatomy Contributes to Regulation of the Neuronal Ionic Microenvironment. A prominent feature of glial cells in crustacean (but not insect) central nervous system connectives is a system of transcellular tubules called the *tubular lattice,* which is accessible to extracellular tracers (Lane and Abbott, 1975; Lane et al., 1977). The rapid clearance of potassium away from the axon following repetitive activity has been attributed to this tubular system (Shrager et al., 1983). In the retina of the honeybee drone, uptake of potassium and chloride by the glial cells helps to regulate the neuronal microenvironment during periods of photoreceptor stimulation (reviewed in Coles, 1989; Coles and Schneider-Picard, 1989; Coles et al., 1989).

Axon-Glial Anatomy in Crustacea Permits Chemical Signaling from Axon to Glial Cell. The giant axons of squid are closely invested by a glial (Schwann) cell sheath, and a neurotransmitter cascade is involved in axon-Schwann cell signaling (see below). A similar geometry around crustacean giant axons within the central nervous system connectives proves also to permit axon-glial signaling (Smiley and Lieberman, 1980; Lieberman et al., 1981). These studies have helped to establish the generality of chemical signaling between axons and their surrounding glial cells, recently extended to vertebrates (see Chapter 31).

Lower Mollusks

Lower Molluskan Glia Have a Variety of Morphologies and Associations with Neurons. In lower mollusks, the neural ganglia follow a common pattern, with neuronal cell bodies clustered at the periphery and the synaptic neuropil concentrated at the core. There are no vascular networks within the ganglion, but blood spaces may occur around the cell bodies. As in insects and Crustacea, glial types are mainly identified according to location and morphology, with "plasmatic" or "protoplasmic glia" mainly at the periphery, and "fibrous glia" mainly associated with axonal tracts (Radojcic and Pentreath, 1979). There is no clear equivalent of the *perineurium* of arthropods. Glia associated with large-neuron somata invaginate as trophospongium. In bivalves such as the freshwater mussel *Anodonta,* there are very few glial cells interspersed between axons (Treherne et al., 1969; Lane and Treherne, 1972) (Figure 6-6).

Lower Mollusks Lack a Blood-Central Nervous System Barrier. Electron-dense tracers have been used to show that the blood-central nervous system interface is leaky in the bivalve *Anodonta* (Treherne et al., 1969; Lane and Treherne, 1972; Sattelle and Howes, 1975) and in several gastropods (Mirolli and Crayton, 1968; Pentreath and Cottrell, 1970; Reinecke, 1975, 1976). Studies with lanthanum are complicated by the fact that the charged tracer appears to be excluded from (charged) fibrillar zones within the extracellular space. Ion-substitution experiments in freshwater gastropods and bivalve nervous systems confirm that the interface is relatively open (Sattelle, 1973), but show that in some cases neuronal function can continue in a low-sodium medium, possibly supported by a local glial sodium store (Treherne et al., 1969) (Figure 6-6). An analogous calcium ion store has been proposed in the marine mollusk *Aplysia* (Keicher et al., 1992).

Anatomical Relations Underlie Neuron-Glial Interaction in Molluskan and Annelid Ganglia. The close glial ensheathment of neurons, with trophospongial

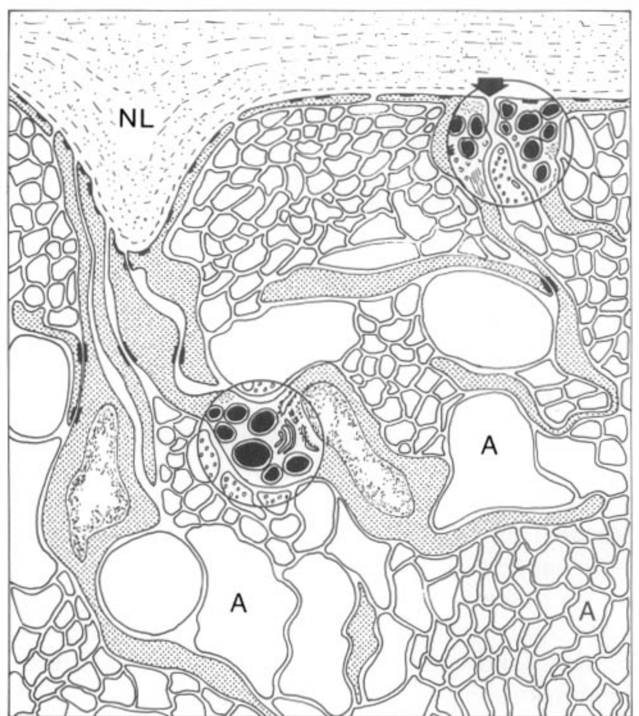

FIG. 6-6. Glial cells (*shaded*) and axons (*A*, *unshaded*) of the cerebrovisceral connectives of the central nervous system in the freshwater mussel, *Anodonta cygnea* (Lamellibranchiata, Mollusca). The circles highlight fine-structural detail. Note the lack of junctional specializations between the cells of the outer glial sheath (*arrow*, absence of diffusion barrier), and presence of dark granules in glial associated with the larger axons, that may represent an intracellular sodium store. The dark bars are desmosomes and hemidesmosomes providing mechanical coupling between glia cells, and between glia and neural lamella (*NL*) respectively. [Based on Treherne et al. (1969), with permission.]

invaginations, permits a range of short-range interactions between neurons and glia. Autoradiographic techniques have provided evidence for trophic support of neurons by glia, and for modulation of this support by signals liberated by neurons (Pentreath, 1982; Pentreath and Pennington, 1987).

Cephalopod Mollusks

Cephalopod Glial Cells Have Complex Morphologies. Coleoid cephalopods include squid, octopus, and cuttlefish, marine mollusks with highly developed nervous systems able to compete successfully with other marine predators, such as fish. Cephalopods are the only invertebrate group with a completely closed vascular system, formed by a continuous vessel network within the tissues.

The morphologies of cephalopod glial subtypes show many similarities with those of higher vertebrates. Lenhossèk (1896) described "bushy glial cells" in the plexiform zone of the optic lobes of cephalopods, the first clear demonstration of branching neuroglia in any invertebrate. Ramón y Cajal (1917) who had done so much to demonstrate the glial types in mammalian brain, confirmed the plexiform zone glia of cephalopods, and also described "epithelial cells" surrounding neurons in the outer granule layer of the optic lobe and "protoplasmic astrocytelike cells" throughout the lobe. Cells like fibrous astrocytes were seen by Gariaeff (1909) around neuronal perikarya and invaginating them as trophospongium. Young (1971) applied many of the classical gold and silver staining techniques of Golgi, Ramón y Cajal, and later histologists to the octopus brain, and succeeded in a very detailed mapping of the neurons and their connections; under some conditions the stains showed glial cells rather clearly. Classes of *protoplasmic glia* associated with neurons and *fibrous glia* associated mainly with axon tracts could be distinguished. Cardone and Roots (1990) showed glial fibrillary acidic protein (GFAP) immunoreactivity in both octopus and snail brain.

Certain Glial Cells Are Associated with Cephalopod Blood Vessels and the Glio-vascular System. Bogoraze and Cazal (1944) were the first to describe a close association between one class of cephalopod glial cell and the blood vessels. Stephens and Young (1969) confirmed the association between glia and vessels, and described a "gliovascular" system of glial-lined spaces radiating from the perivascular space deep into the octopus brain. Electron microscopy of the gliovascular system (E. Gray, 1969) showed that it contained collagen, smooth muscle cells, and fibrocytes, suggesting it might play a dynamic role in the movement of interstitial fluid. Grapelike clusters of "lymphoid" spaces around venous channels (Stephens and Young, 1969) could act as the drainage route by which fluid returned to the venous system. In the cuttlefish *Sepia officinalis*, the gliovascular system is not prominent in the vertical and optic lobes, although there are expansions of the extracellular space, particularly around arteries (Bundgaard and Abbott, 1992). However, there is good radiotracer evidence for a flowing interstitial fluid in *Sepia* (Abbott et al., 1985), suggesting the interstitial spaces present are sufficient to sustain the flow.

There are some instructive parallels with the mammalian brain. The vertebrate central nervous system lacks the lymphatic vessels found in other tissues, and it was originally assumed that fluid drainage was entirely via cerebrospinal fluid into arachnoid villi and hence into cerebral veins. However, it is

now clear that perivascular spaces may act as low-resistance pathways for interstitial fluid flow in mammalian brain, and that up to 50% of the interstitial fluid and cerebrospinal fluid may leave the brain via this route, connecting to the cranial nerves and lymphatics of the neck (Bradbury and Cserr, 1985; Ichimura et al., 1991). A system of glial-lined spaces filled with flowing interstitial fluid may then be a feature of both invertebrate and vertebrate brain; a flowing interstitial fluid permits more effective ionic homeostasis, distribution of neuroactive compounds (e.g., modulator peptides), and removal of wastes than does a stagnant system (Abbott et al., 1985).

Glial Cells Contribute to the Cephalopod Blood-Brain Barrier. Early electron microscopic studies by Barber and Graziadei (1965, 1967) identified two classes of cell forming the wall of octopus cerebral blood vessels, endothelial cells, and pericytes, but as neither layer was invariably complete, they concluded there was no blood-brain barrier. More rigorous study of the optic and vertical lobes in the cuttlefish *Sepia* showed that a continuous (and in many cases "seamless") layer of perivascular glial endfeet was always interposed between the blood and the neurons, except in the case of neurosecretory cells (Bundgaard and Abbott, 1992). Studies with electron-dense tracers horseradish peroxidase and lanthanum showed that these molecules met diffusional restriction at the glial level (Abbott and Bundgaard, 1992). Thus in the microvessels, glial cells form the blood-brain barrier of the cuttlefish (Figure 6-7). Studies on the squid and octopus confirm the same pattern (Bundgaard et al., 1994), which therefore is likely to apply to all coleoid cephalopods. In arteriolar vessels the diffusional restriction is formed by the (mesodermal) pericyte layer (Abbott and Bundgaard, 1992). The barrier in cephalopods appears not to be due to conventional tight junctions (*zonulae occludentes*), but rather is achieved with little narrowing of the intercellular cleft. Periodic electron-lucent "linker" structures spanning the cleft, and a dense extracellular matrix may together be responsible for the diffusional restriction, a novel type of occluding junction (Abbott et al., 1992a; Bundgaard et al., 1994). The axons connecting the *Sepia* optic lobe to the retina are accessible to horseradish peroxidase and hence lack a barrier (Abbott et al., 1986b).

The Cephalopod Blood-Brain Barrier Gives Insights into the Evolution of the Vertebrate Blood-Brain Barrier. The presence of a blood-brain barrier in insects, Crustacea, and cephalopod mollusks—but the lack of a barrier in lower invertebrates—led to the suggestion that a barrier is needed for the more complex kinds of integrative and analytical activity of the nervous system (Abbott et al., 1986a). It was proposed that the evolutionary pressure to develop a barrier came from the need to preserve ionic homeostasis around the synaptic zones responsible for central integration, given the vulnerability of "graded" synaptic potentials to fluctuations in the ionic composition. This idea is strengthened by the observation

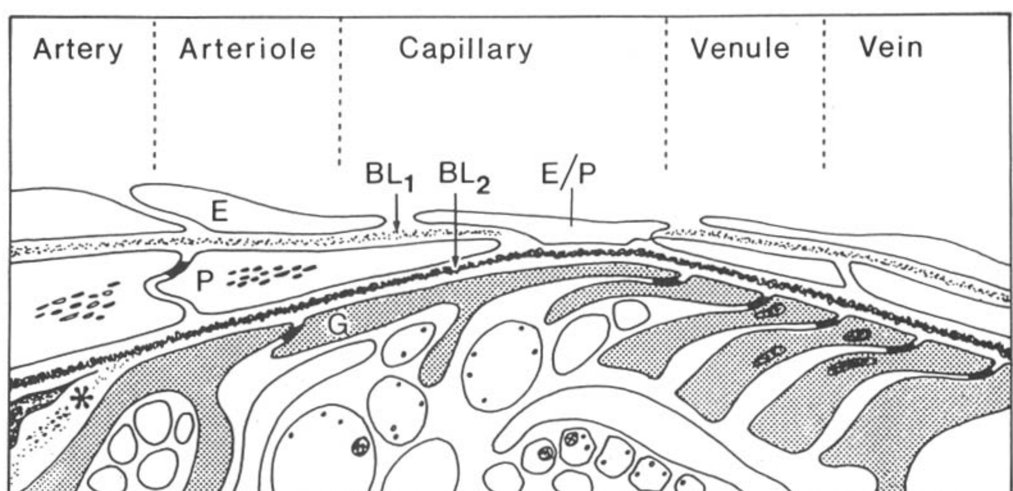

FIG. 6-7. The blood-brain interface in the cuttlefish *Sepia officinalis* (Cephalopoda, Mollusca). Schematic diagram (not to scale) from the arterial to venous end of the microvasculature, based on electron microscopy of the vertical and optic lobes of the brain. *E*, endothelial cell; *P*, pericyte; BL_1 and BL_2, basal laminae; *G* (*shaded*), perivascular glial layer; *asterisk*, collagen-filled extracellular space. In the smallest vessels, only a single class of endothelial/pericyte (*E/P*) can be seen. Black bars between cells show occluding juctions. The blood-brain barrier is formed by glia in the capillaries and venules, and by pericytes in arterioles. [From Abbott and Bundgaard (1992), with permission.]

that axons, conducting "all-or-none" action potentials do not need such fine control, as shown by the absence of a blood-nerve barrier in crustacean, cephalopod, and small insect nerves.

The presence of a glial barrier in invertebrates and a primitive vertebrate group the elasmobranchs (see below) together with the presence of glial-ependymal barrier in higher vertebrate brains in early embryonic stages suggests that a glial barrier is the primitive condition, and an endothelial barrier as found in higher vertebrates, including mammals, is a later evolutionary feature. The pericyte layer of cephalopod arterioles may then represent an intermediate transition stage (Abbott, 1992). The "linker junction" of the cephalopod blood-brain barrier also shows some features seen in glial junctions of the embryonic vertebrate neural tube (Møllgård et al., 1987), and in the wider parts of the junctional zones in mammalian endothelia (Firth et al., 1983). Thus the location and fine structure of the cephalopod barrier junction can give useful insights into the evolution of occluding junctions in general, and the blood-brain barrier in particular (Abbott, 1991, 1992).

Schwann Cells Associated with the Squid Giant Axon Are Involved in Axon-Schwann Cell Signaling and Coordination. In most vertebrates, the Schwann (glial) cells around peripheral axons are too small for physiological study *in situ,* so that most information comes from dissociated and cultured cells (see Chapter 51). The Schwann cells of the giant axon of the squid are relatively accessible and large (cell bodies around $70 \times 20 \times 1$ μm), with elongated processes running along the axonal axis (Brown and Abbott, 1993). They have a prominent system of transcellular tubules (glial tubular system) like the tubular lattice of crustacean adaxonal glia (Zwahlen et al., 1988; Brown and Abbott, 1993) and the intercellular cleft has a restriction at the axonal end where a single strand of intramembranous particals is seen in freeze-fracture replicas (Zwahlen et al., 1988). Electron-dense tracers in the bathing medium are able to penetrate the glial tubular system and reach the periaxonal space (Brown and Abbott, 1993). Morphometric studies show that the tubular system is likely to be the predominant route for extracellular ion flux (Zwahlen et al., 1988; Brown and Abbott, 1993).

The size of the squid Schwann cells and axons has permitted microelectrode recording and pharmacological and biochemical study. There is evidence for a "transmitter cascade" of chemical signaling from axon to Schwann cell (Villegas, 1984; Lieberman et al., 1989; Evans et al., 1991), capable of switching the Schwann cell from a quiescent to an activated state following axonal activity (see Chapter 31). There is also evidence for a trophic role of Schwann cells on the giant axons, specifically in the transfer of proteins (Lasek and Tytell, 1981; Buchheit and Tytell, 1992).

NONMAMMALIAN VERTEBRATE GLIAL CELLS

Evolution of Glial Structure and Function

Figure 6-8 shows a vertebrate evolutionary tree. The morphology and function of glial cells in lower vertebrates can give clues to glial evolution, and help to explain the origin of patterns seen in higher groups. The vertebrate neural tube is derived from ectoderm, and in many lower vertebrates, the epithelial nature of glia remains prominent. In the primitive neural tube, glial cells or their precursors span from pial to ventricular surface, forming the radial glia (see Chapter 4). Cells with processes extending back from the ependyma but not attached to the pia are termed ependymal tanycytes. In mammals and birds, radial glia are a transient population forming a scaffold for migration of neuroblasts to their final locations, and largely transformed into astrocytes in the adult (Voigt, 1989; Misson et al., 1991). Radial glia and tanycytes are retained into the adult in many lower groups (reviewed in Roots, 1986), along with other glial epithelial features: barrier-forming

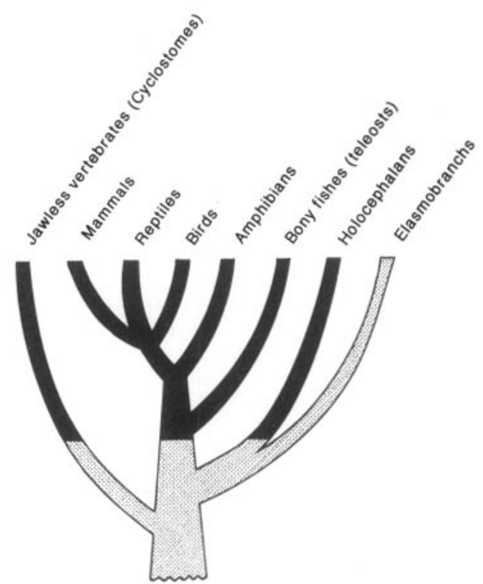

FIG. 6-8. Evolutionary tree of vertebrates; the base is approximately 500 million years ago, the tips of the branches represent present time. *Stippled area*, glial blood-brain barrier; *black area*, endothelial barrier. [From Abbott, (1992), based on Cserr and Bundgaard (1984), with permission.]

potential, desmosomes, and intermediate filaments closely related to those of the skin. The relations between hematogenous cells and glia in teleost fish highlight some important features of the immune system in the brains of higher groups.

Fish: Cyclostomes, Teleosts, and Elasmobranchs

Cyclostomes Have Epithelioid Glial Cells. Cyclostomes, the class of Agnatha that includes the lamprey and hagfish, diverged from mainstream jawed vertebrates in pre-Carboniferous times (>300 MYr ago). Their central nervous system shows several primitive features, including the retention of Rohon Beard cells in the adult (reviewed in Scholes, 1991; Scholes et al., 1992). They have almost no myelin, and, correspondingly, few oligodendrocytes. The neural tissue is vascularized chiefly at its surface, with very few penetrating vessels; they are absent in spinal cord. The astroglia have a similar radial form throughout the central nervous system, linked by desmosomes and full of intermediate filaments, which are not immunoreactive for GFAP (Dahl and Bignami, 1973; Dahl et al., 1985).

The Teleost Optic Nerve Retains Primitive Features to Cope with Physical Stress. In the embryology of the vertebrate optic nerve, the germinal (ependymal) zone is lost as a result of the "sculpting" process of selective cell death. The avascular optic nerves of bony fish (teleosts) contain a single class of unusual "reticular" astrocytes, which retain their radial orientation, but now connect pial surfaces and form a series of lacelike partitions through which the axons run (Maggs and Scholes, 1990) (Figure 6-9). The movements of the eyes impose large stresses on the teleost optic nerve, and several anatomical specializations result. Nerve axons display a zigzag pattern, allowing length changes, and the reticular astrocytes provide a scaffold, maintaining the organization, and possibly imposing periodicity on nodal distribution (Scholes, 1991). The reticular astrocytes also segregate axons in the left and right optic tracts, leading to the completely crossed optic chiasm unique to fish (Scholes et al., 1992). The astrocytes are linked by desmosomes and contain cytokeratins (Giordano et al., 1989; Druger et al., 1992) rather than the GFAP filaments characteristic of higher groups, and in this they resemble both the floor plate cells of the developing amphibian neural tube

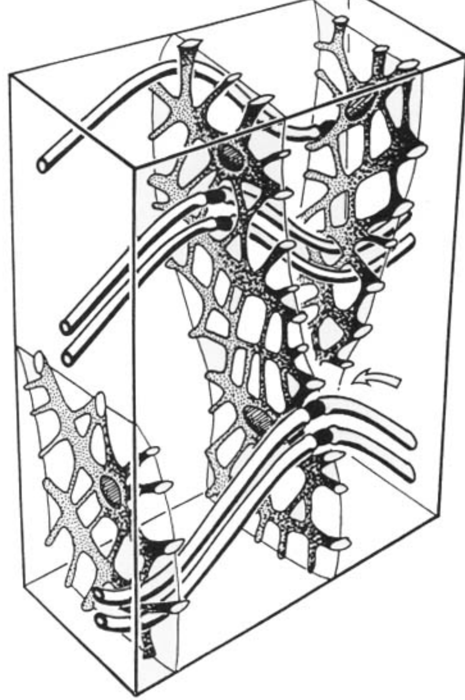

FIG. 6-9. **(A)** Arrangement of the reticular astrocyte network in the ribbon optic nerve of the cichlid teleost fish. The *large black arrow* shows the direction of the optic fibers. *g.* indicates the germinal margin of the ribbon, in which preastrocytic cells have fine lamellar processes running longitudinally as indicated, through distances equivalent to several partition repeats. **(B)** The relations between reticular partitions (*stippled*), the nerve fiber waves, and the nodes of Ranvier (*arrow*) in the chichlid optic nerve. The oval structures (hatched) are astrocyte nuclei. [From Scholes et al. (1992), with permission.]

(Holder et al., 1990) and the cells of the skin. Retaining a more epithelioid phenotype in the fish optic nerve glia allows the nerve to preserve elasticity and resistance to stretch, no longer needed in the brain enclosed in a bony skull. Interestingly, GFAP expression increases in the optic nerve after injury (Stafford et al., 1990), suggesting that reactive glia can recruit from a phenotype closer to that of the brain.

Fish Myelin Holds Clues to Myelin Evolution. Skate (elasmobranch) and teleost brains contain myelin proteins with close similarities to P_0, the myelin protein found only in the peripheral nervous system of higher vertebrates (Jeserich and Waehneldt, 1987; Jeserich et al., 1990; reviewed by Kirschner and Blaurock, 1992). Fish thus mark the transition from P_0 to proteolipid protein (PLP) as the major myelin protein component (see Chapter 38).

Teleost Brain Contains Large Numbers of Glial-Associated Hematogenous Cells. The teleost central nervous system has three main classes of glial cell, oligodendrocytes, ependymal tanycytes, and radial glia (Wolburg and Bouzehouane, 1986; Sivron et al., 1992). Fish have a relatively weak immune system, having not yet developed the germinal zones for hemopoetic tissue in bone marrow and lymph nodes, nor the ability to make high-affinity antibodies as in higher vertebrates (Du Pasquier, 1992). In mammalian brain, cells derived from blood (e.g., lymphocytes, macrophages) are present in small numbers, generally associated with sites of inflammation. By contrast, hematogenous cells are numerous in teleost brain, and are found associated with glia, not neurons (Dowding and Scholes, 1993). The associations are particularly clear in the optic tectum, which has a marked vertical layering segregating white and gray matter and other zones (Figure 6-10). Macro-

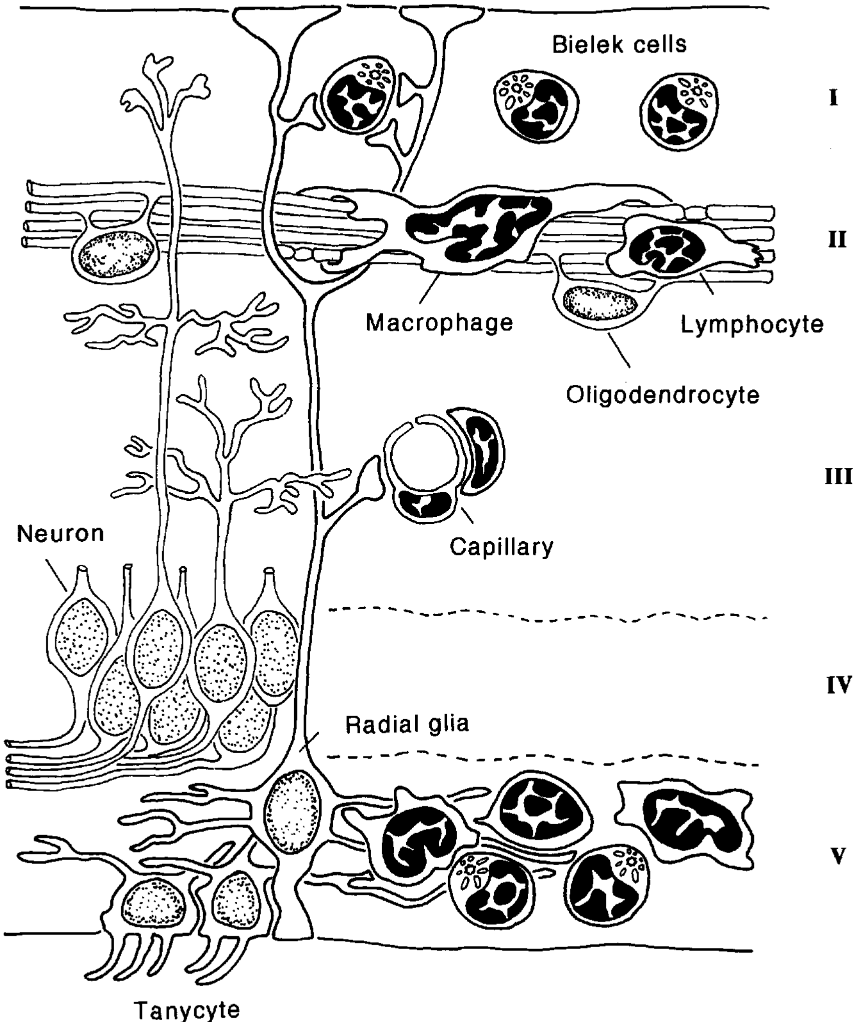

FIG. 6-10. Cell types in the teleost optic tectum. Fish lack the regular networks of ramified microglial cells found in the central nervous system in mammals. Instead, varied hematogenous forms of leukocytes are present in large numbers in the brain and spinal cord, associated with glia not neurons. This diagram shows their localization determined immunocytochemically and by electron microscopy (Dowding and Scholes, 1993) in the optic tectum, whose orderly vertical layering displays the specificity of these associations.

The leukocytes are clustered in three of the five strata (I–V) of the tectum, as follows: *I*, the *stratum marginale*, contains mainly Bielek cells, a special category of leukocyte found in the hematogenous organs and central nervous system in fish. Here they are ringed by endfeet of the distal processes of the radial glia, the *stratum opticum*, composed of dense fascicles of myelinated afferent fibres. Numerous macrophages and lymphocytes are specifically associated with the myelin here and elsewhere in the central nervous system: in spinal cord white matter they outnumber the oligodendrocytes. *V*, the *subependyma*, a glial plexus formed by radial glia and tanycytes which contains numerous leukocytes of different types, mainly lymphocytes and Bielek cells. By contrast, all types of leukocytes are rare in the neuropil and nerve cell layers of the tectum (strata III and IV). The association of radial glial endfeet with capillaries is shown. [By permission of J Scholes, unpublished data.]

phages congregate in white matter, where they remove myelin debris. A class of leukocyte, the Bielek cell, is strongly associated with glial end feet in the marginal zone (strium marginale) and subependymal plate, an association that may be designed to prevent their free passage into the neuronal zones, or to facilitate immune interactions. The subependymal plate also contains large numbers of lymphocytes and macrophages.

The Teleost Central Nervous System Has Strong Regenerative Capacity. The fish central nervous system has a strong capacity for regeneration and repair (Attardi and Sperry, 1963; Schwartz et al., 1985; Battisti et al., 1992), possibly associated with the numbers and efficiency of hematogenous macrophages. The system may only work well because fish have not evolved mechanisms for generating high-affinity antibodies. The relative segregation of the higher vertebrate nervous system from hematogenous cells, with myelin housekeeping passed over to microglia and astrocytes, may give the brain of higher vertebrates greater protection from autoimmune attack, but at the expense of the loss of repair capacity (Dowding and Scholes, 1993).

Elasmobranchs Preserve Many Primitive Evolutionary Features. Elasmobranchs are the dominant group of extant cartilaginous fish (Class Chondrichthyes). They preserve several primitive features including the anatomy of the heart and gill arches, and aspects of digestive and autonomic physiology, although modern elasmobranchs show a great range of "advanced" and "primitive" characteristics. The brain is also relatively simple in structure, with a straightforward linear organization of prosencephalon (telencephalon and diencephalon), mesencephalon, and rhombencephalon, and an absence of surface convolutions over the cortex and cerebellum (Smeets et al., 1983). Tanycytes are a prominent class of elasmobranch glia found throughout the central nervous system (Horstmann, 1954).

The Elasmobranch Blood-Brain Barrier Is Formed by Perivascular Glial Cells. In the major vertebrate groups, the blood-brain barrier is formed by endothelial cells (Figure 6-8, see below). However, elasmobranchs resemble the invertebrate pattern, in having a glial blood-brain barrier (Brightman et al., 1971; Bundgaard and Cserr, 1981) (Figure 6-8). The endothelial junctions are leaky to horseradish peroxidase and show interrupted strands of intramembranous particles in freeze-fracture replicas, while the endfeet of perivascular glial cells are coupled by tight junctions (Figure 6-11) that exclude horseradish peroxidase and show dense networks of intramembranous particles (Gotow and Hashimoto, 1984). The glia limitans under the pial surface is also coupled by tight junctions, so that the brain is effectively sealed in behind a wall of glial cells on both its parenchymal and its pial surfaces.

In most vertebrates a glioependymal barrier is present in the developing neural tube (Møllgård et al., 1987), but disappears later in development. It is intriguing that in glial morphology, as with some other tissue characteristics, elasmobranchs preserve embryonic vertebrate features, adding weight to the idea that in certain situations "ontogeny repeats phylogeny" (Abbott, 1991, 1992). Young (1950) has argued that elasmobranchs have been so successful as large marine predators that they have not been subjected to the same evolutionary pressures as other groups, which may explain the retention of the primitive features. The ratfish *Chimaera monstrosa*, representative of the other main group of cartilaginous fish, the Holocephali, has an endothelial blood-brain barrier (Bundgaard, 1982; Cserr and Bundgaard, 1984) (Figure 6-8).

The Blood-Brain Barrier Glia of Elasmobranchs Retain Glial Properties While Controlling Blood-Brain Exchange. This volume documents the ways in which glial cells help to maintain a proper environment for neural development and function. It is of interest to establish whether the blood-brain barrier glia of elasmobranchs share these properties, or whether they have had to abandon their glial characteristics in order to function as a barrier controlling blood-brain exchange. Radiotracer methods have been developed for studying the permeability and transport of the mammalian blood-brain barrier, and can be easily modified for elasmobranchs (Abbott et al., 1988a). It is found that the glial barrier expresses glucose and leucine transporters (as does the mammalian brain endothelium), and hence is able to maintain the necessary supply of metabolic substrates and essential amino acids to the brain. However, whereas the mammalian brain endothelium shows negligible uptake of neurotransmitter molecules such as glutamate and GABA, there is a detectable uptake by the elasmobranch barrier (Abbott et al., 1988b). Glia in close association with neurons in most animal groups show transporters for amino acid transmitters including glutamate and GABA, so it is clear that the elasmobranch glia retain some 'gliallike' properties in spite of their barrier role. Since one of the functions of any blood-brain barrier is to exclude from the brain neuroactive substances circulating in the blood, it is likely that glutamate and GABA taken up by the

FIG. 6-11. elasmobranch glial barrier will be broken down intracellularly, effectively preventing their penetration into the brain. Thus endothelial and glial barriers achieve the same end, but by different means (Abbott, 1991). Retinal glia in elasmobranchs show a similar distribution of potassium channels to those of teleosts and amphibia, suggesting they are also able to mediate potassium spatial buffering (Newman, 1988).

Amphibians and Reptiles

Glial Cells of Amphibians and Reptiles Have a Strong Radial Morphology. Amphibia and reptiles are poikilothermic (coldblooded) vertebrates, with a relatively simple nervous system, on a similar plan to that of higher groups such as mammals and birds, but with a less complex cortical structure and simpler organization of sensory and motor systems. Radial glia and tanycytes are retained in the adult (Monzon-Mayor et al., 1990). Within the retina are found the specialized "Müller" glial cells spanning from receptor layer to vitreous (see Chapter 4). Cells of the glioependyma form a system of channels in the spinal cord along which axons grow, in development and regeneration (Singer et al., 1979; see Chapters 27 and 60, this volume). In the optic nerve of the mudpuppy *Necturus,* glial cells form a surface layer, extending inward as partitions between the axon bundles (Figure 6-12). The relatively large size of amphibian glia, their accessibility, and their robustness has meant that amphibian glia have provided some excellent experimental preparations for electrophysiological study (see Chapters 31 and 37).

Birds

Glia of Birds and Mammals are Similar. The large and accessible eggs of birds have been useful in embryological and experimental studies. The complexity of the avian nervous system approaches that of mammals, and the similarities of anatomy make for ready extrapolation to the mammalian system (Roeling and Feirabend, 1988). However, many antibodies developed as markers for mammalian glia do not cross-react with birds, so the homologies are not always clear.

The Avian Embryo Gives Information About the Role of Glia in Development. The developing nervous system of the chick can be observed through the transparent membranes of the chorioallantois, and detailed

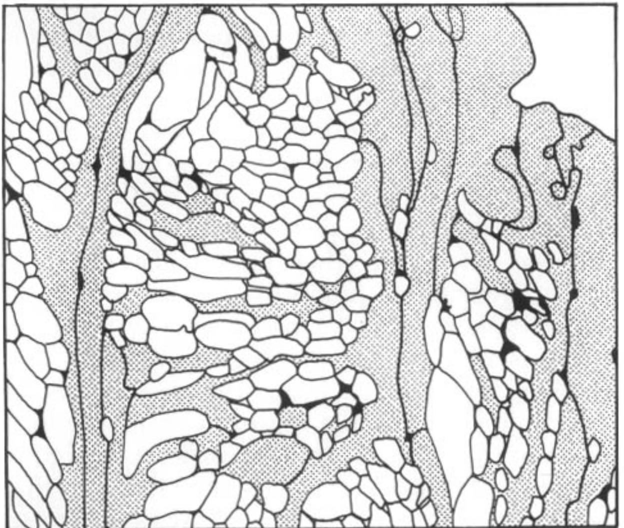

FIG. 6-12. Tracing of an electron micrograph of the glial cells (*shaded*) and axons at the surface of the optic nerve in the mudpuppy *Necturus* (Amphibia). The large size of the glial cells and their accessibility permits microelectrode penetration and physiological study. After enucleation, the axons degenerate, leaving a "glial nerve." [From Kuffler et al. (1966), with permission.]

observations and fine experimental manipulation are possible. Retrovirus-mediated gene transfer has been used to map the lineage of cells of the nervous system and show the common origin of astrocytes and neurons and their migration paths (Galileo et al., 1990; G. Gray and Sanes, 1991, 1992). The glia of the eye are particularly suitable for experimental manipulation.

Avian Glia Induce a Blood-Brain Barrier in Endothelial Cells. The avian system has also been instrumental in studies on blood-brain barrier induction. In higher vertebrates, including birds and mammals, the blood-brain barrier is formed by endothelial cells, but inductive factors from the nervous system are required. Grafting studies taking advantage of quail-chick chimeras showed clearly that if small pieces of donor brain were grafted into non-brain tissue of the host, the graft became vascularized by the host (Stewart and Wiley, 1981). The fact that the vessels in the graft developed blood-brain barrier properties is evidence for an inductive influence from neural tissue. Astrocytic clusters grafted onto the chorioallantoic membrane of the chick also became vascularized from the host, and again the vessels became tighter, evidence that astrocytes are responsible for at least part of the inductive influence (Janzer and Raff, 1987; see Chapter 50, this volume).

SUMMARY: COMPARISON OF MAMMALIAN AND NONMAMMALIAN GLIA

Glial Subtypes and Classification

In the earliest histological studies using classical silver and gold staining techniques, a great range of glial morphologies was described, but it was not known whether these represented different classes of glia. A general division into fibrous and protoplasmic astrocytes, oligodendrocytes, and microglia could be made on the basis of gross morphohology, location, and relation to neurons and blood vessels. The introduction of immunocytochemical methods and specific antibodies, together with molecular approaches to the question of cell lineage, allowed some generalizations about the relations and developmental sequence of glial types. The recent demonstration of differences in receptor and transporter expression on glial cells from different parts of the nervous system, has caused renewed interest in the possibility that individual glial cells may have phenotypes as varied as those of neurons, and in many cases this will be reflected in their morphologies. Lower vertebrate and invertebrate preparations offer the possibility of working with glial cells associated with identified neurons, something not yet practical for vertebrate glia *in situ*.

Role of Glia in Development and Regeneration

This survey of glia in different animal groups from invertebrates to birds has shown that glial cells play important roles in development by providing morphological landmarks and channels, by expressing surface molecules favourable for adhesion, and by secreting growth factors that stimulate proliferation and outgrowth. In lower animals many of these features are retained in the adult, permitting some regeneration, an ability largely lost in mammals. The strong macrophage involvement in the response to injury in lower vertebrates may also contribute to conditions favoring regeneration. Understanding the mechanisms used by lower vertebrates could lead to remedial strategies for neural repair in mammals, including humans.

Role of Glial Morphology in Regulation of the Neuronal Microenvironment

In both higher and lower groups, the morphology of glial cells confers certain properties that help them regulate the ionic environment. Thus the endfeet of perivascular glial cells, by "siphoning" potassium from neurons to the blood vessel wall may permit coupling between neuronal activity and cerebral

blood flow (Paulson and Newman, 1987). The vitread process of the retinal Müller cell, with its high density of inward rectifier potassium channels, permits operation of the potassium "spatial buffer" in the retina, and the fine astrocytic process apposed to the nodes of Ranvier may have an equivalent function in central nervous system white matter. The segregation of groups of axons and synapses by glial partitions may allow functional compartmentation and reduce "cross talk."

Role of Glial Cells in Synaptic Zones in Neurotransmitter Uptake and Recycling

In synaptic zones within the nervous system, space is at a premium, and nerve terminal processes are packed tightly together to make maximum use of the areas for membrane:membrane contact. The close association of glial cells with synaptic zones underlies two functions, morphological segregation of synaptic inputs (as in "glomeruli") and chemical segregation, by the presence of transport mechanisms capable of rapidly removing transmitter from the extracellular space. Glial cells may occupy as much as 50% of the vertebrate central nervous system volume and outnumber neurons by 10:1 (Nicholls et al., 1992); this implies a much greater surface area of glial than neuronal membrane, an optimal arrangement for providing transporters on glial membranes close to synaptic sites.

Role of Glial Cells in the Blood-Brain Barrier

All higher animals possess a blood-brain barrier, which is formed by glial cells in invertebrates and elasmobranchs, and by endothelial cells in higher vertebrates. Evolutionary and developmental considerations suggest that a glial barrier is the primitive condition, and the shift to an endothelial barrier is one aspect of the greater division of labor between cell types seen in the central nervous system of higher animals. Where the barrier is now endothelial, glial cells are still important in inducing and maintaining the barrier, which makes sense of the close association between glial endfeet and vessel, and helps explain breakdown of the barrier in some glial tumors and other central nervous system pathologies where the inductive influence is disturbed (reviewed in Abbott et al., 1992b).

Polarity and Barrier-Forming Potential of Mammalian Glia

Where glial cells form an epitheliallike layer in invertebrates, for example, in the perineurium of arthropod ganglia and connectives, and the perivascular barrier glia of the cephalopod brain, there is a clear polarity to the cell, the basal surface secreting a prominent basal lamina, and the apical end frequently demonstrating surface specializations, such as elongated processes running into the nervous tissue. Where cell:cell junctions occur, they are generally close to the apical end of the lateral intercellular space, as in other epithelia. The glial cells and undifferentiated primordial cells of the vertebrate central nervous system express clear polarized properties in certain locations, for example, the ependyma, glia limitans below the pia, retinal pigment epithelium, choroid plexus epithelium, radial glia and tanycytes, and Müller cells of the retina (reviewed in Abbott et al., 1986a). Astrocytes that have lost contact with the pial or ventricular surface of the vertebrate central nervous system may nevertheless retain a functional polarity (e.g., basal endfeet on blood vessel and apical processes associated with neurons) (Bradbury, 1979). As better morphological markers are developed for looking at regional differences in glial membranes, this functional polarity is likely to take on increasing significance, showing that differences in function are not only seen between different glial types, but also between different cells within a class, and between different parts of the cell membrane of a single glial cell (Reichenbach, 1989; Holder et al., 1990). Throughout the history of glial studies, the close relations between glial morphology and glial function have been a continuing and productive theme.

Relative Roles of Glia and Hematogenous Cells

In teleost fish, the brain contains large numbers of macrophages that service myelin and leukocytes associated with ependymal tanycytes and radial glia; the brain has good regenerative capacity. In higher vertebrates, hematogenous cells are largely excluded from the brain, myelin debris is removed by the resident macrophages (microglia) and by astrocytes, and there is minimal capacity for regeneration. The transfer of function from hematogenous cells to macroglia and microglia is associated with increasing sophistication of the immune system, and increasing isolation of the nervous system from the blood compartment. This evolutionary pattern may have been necessary to reduce the risk of autoimmune attack on the nervous system, but the ability to repair central nervous system damage may have been sacrificed in the process (Dowding and Scholes, 1993).

II Lineage

This page intentionally left blank

7 Methods of studying glial cell lineage

JACK PRICE

Glial cells, like neurons, are derived from embryonic neuroepithelial cells. In the central nervous system, these neuroepithelial cells belong to the neural plate; in the peripheral nervous system they are the cells of the neural crest and the placodes. The neuroepithelium is initially a simple pseudostratified epithelium in which all the cells are dividing and all apparently behave the same. As development proceeds, however, the behavior of the neuroepithelial cells changes. Some cells stop dividing and begin to migrate from the neuroepithelium. These are the first neurons, and in most areas of the neuroepithelium their production dominates the embryonic period. The onset of gliogenesis is more difficult to identify precisely, but for most areas of the nervous system the main period of glial production follows neurogenesis, the production of oligodendrocytes usually following that of astrocytes. The cerebral cortex of a newborn rat, for example, is composed predominantly of neurons, but 2 weeks later there are many more glia than neurons (Parnavelas et al., 1983). It is also generally true that the glial cells are not generated directly from the neuroepithelial cells, but rather via intermediate precursor cells, such as those that make up the subventricular zone in the cerebral cortex (Wood and Bunge, 1984).

This pattern of development poses a number of problems. The neuroepithelial cells have the potential to generate glia, yet this potential is not expressed until most of the neurons have been produced. Our ultimate goal, of course, is to understand how these processes are controlled in cellular and molecular terms, but the aim of the studies discussed in this chapter is more modest. A first step toward understanding nervous system histogenesis is to understand what "fate" decisions are being taken by cells at any given point in development, and how these decisions alter their behavior. This brings us to the topic of cell lineage.

Cell lineage is concerned with how different cell types are related. Its significance becomes clear if we consider the generation of cellular diversity in terms of two alternative scenarios. The neuroepithelial cell population could be made up of cells that are all pluripotential; that is, each cell is capable of generating each of the different cell types. If so, then each neuroepithelial cell could generate neurons for a period, then switch to the production of astrocytes (or their immediate precursors), then switch to the production of oligodendrocytes. If this were the case, the mechanistic problem would be: how is the switching controlled? The second possibility, however, is that neuroepithelial cells themselves are of different types, each dedicated to the production of one type of cortical cell. Thus, initially a neuronal precursor population would be actively generating neurons, while the glial precursors would not produce differentiated cells at all. They would presumably only divide to give more cells like themselves. Later, the neuronal precursor cells would become silent or disappear, and the astrocyte precursors would become activated, followed in their turn by the oligodendrocyte precursors. In this model, there is no switching of cell fate at all, and it would be pointless asking at late stages of development what controls whether a cell gives rise to a neuron or a glial cell, since no precursor cell was making that choice at that time. In order to understand which of these two models (or any of the other theoretically plausible alternatives) is true, we need to know the lineage relationships of the neural cell types. When, for example, do precursor cells cease to generate both neurons and glial cells? Is it late in development as the first model would predict, or early as predicted by model two? To rephrase the question in a testable form: how many different types of precursor cell are there; what do they generate; and how do they change with time?

In this chapter, I describe how cell lineage and the related fields of study are being approached, both conceptually and experimentally, and the picture that is emerging from these studies.

CELL LINEAGE LABELS

The simplest way to discover what a precursor cell will generate is to label it, allow it to develop un-

disturbed, then look at what the marked cell has produced. Two methods have been developed to do this in vertebrate embryos: the direct injection of lineage labels and retroviral vectors.

Injection of Lineage Labels

The most direct method of labeling a cell is to inject it with a marker, usually either a fluorescent compound or an enzyme that can be detected histochemically. A recent innovation has been to use a caged fluorescent marker that requires laser activation, but this has so far only been applied to the study of invertebrates (Vincent and O'Farrell, 1992). As the precursor cell divides, the cells it generates will inherit some of the labeled cytoplasm and so also be labeled. This technique was originally devised to label precursor cells in invertebrates (Weisblat et al., 1978), where the cells are large and easily accessible. It was subsequently applied to amphibian embryos, which also have the advantages of size and accessibility (Jacobson and Hirose, 1978). One of the notable recent technical achievements in this field has been the adaptation of this technique to label the very small precursor cells of amniotes (Bronner-Fraser and Fraser, 1988; Fraser et al., 1990; Lawson et al., 1991). This has contributed to our knowledge of cell lineage in the retina (Holt et al., 1988; Wetts and Fraser, 1988), which will be discussed below, and provided the single most dramatic finding in central nervous system lineage, the lineage compartments of the hindbrain (Fraser et al., 1990).

The principal advantage of the direct labeling approach is its simplicity and its certainty; the number and position of the labeled cells are known precisely. There are, however, a number of potential disadvantages. For instance, the injected substance might be toxic, or the cell might be damaged by the injection. In addition there are two major limitations. First, only precursor cells that are accessible to direct injection can be studied. This currently excludes all neural plate precursor cells in mammalian embryos. The chick neural plate has proved more tractable, however, because of its larger size and accessibility (Lunn et al., 1987; Bronner-Fraser and Fraser, 1988; Fraser et al., 1990). Second, as the clone of cells derived from the injected cell grows, the label becomes more and more dilute. Eventually, the point is reached when it becomes undetectable. Since this point is likely to be before development is complete, this can severely restrict the lineage relationships that can be studied. This presumably explains in part why most the studies using this technique have not addressed the issue of glial lineage in any depth.

Retroviral Vectors

A second way of marking precursor cells is genetically. The idea is that, rather than insert a marker substance by injection, a precursor cell is marked by the introduction of a gene. This has been achieved in insects using x-radiation-induced mitotic crossover (Ready et al., 1976; Lawrence and Green, 1979). Similar methods have been used in mammals (Wikler and Rakic, 1991), but not to study glial lineage as far as I am aware. More recently, genetic labeling has been achieved in mammalian embryos with retroviral vectors.

Retroviruses are a naturally evolved means of gene transfer. Consequently, they are accurate, efficient, and they operate under normal physiological conditions. A normal wild-type retrovirus gets into a cell by receptor-mediated endocytosis (Figure 7-1). Once inside, the RNA genome of the virus is reverse-transcribed to give, ultimately, a double-stranded DNA provirus. This provirus gains access to the infected cell's chromosomal DNA, into which it integrates. For reasons that are improperly understood, integration can only take place into cells that are moving through the cell cycle; postmitotic cells cannot be labeled.

There are two important consequences of viral integration. First, genes encoded by the virus will be transcribed and translated using the cell's normal machinery. A retrovirus carries its own powerful promoter elements (although these can be replaced with others). Thus, it comprises an independent transcriptional unit, which has evolved to give high levels of expression in a wide range of cell types. Second, when the cell carrying the integrated provirus divides, the viral DNA will be inherited unchanged by both daughter cells; it has become a permanent, genetic marker of all the progeny of the labeled cell.

There is, however, a complication associated with integration. Recent work has shown that when a precursor cell is infected, the retroviral marker is inherited by only one daughter at the next division (Hajihosseini et al., 1994). This is apparently because the retroviral DNA integrates into the chromosomal DNA of the infected cell as that cell divides at M phase (Roe et al., 1993). Since the chromosomal DNA has already replicated at this point in the cell cycle, only one daughter cell can inherit the provirus (Figure 7-2A). This has important consequences for retroviral lineage labeling. At a minimum, it means that the lineage has been labeled one cell cycle later than might have been anticipated, but if the precursor cell is dividing asymmetrically, like a stem cell, the consequences are more profound be-

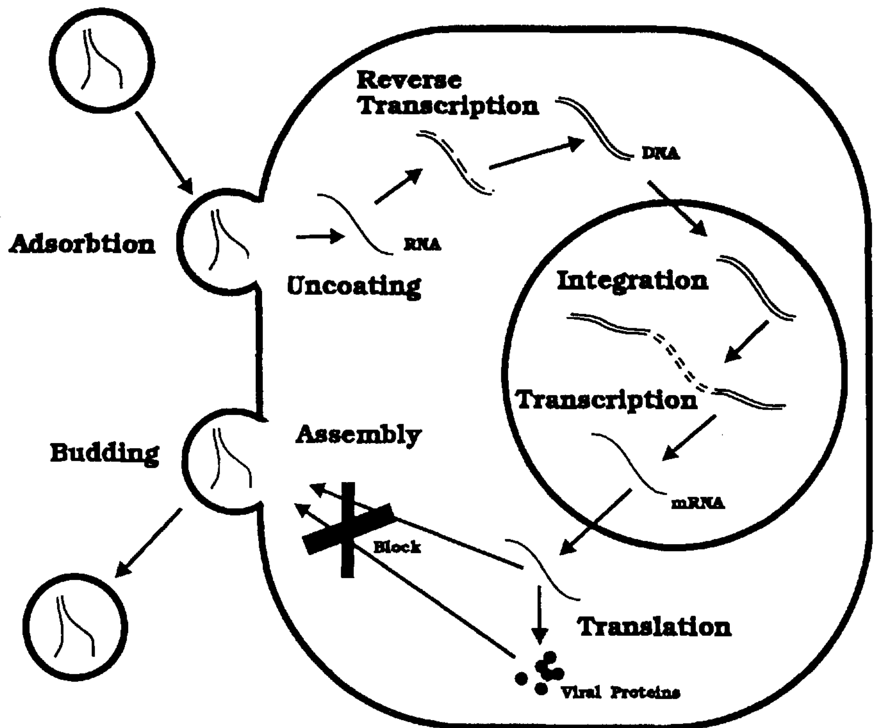

FIG. 7-1. The life cycle of a wild-type retrovirus. A retrovirus is an encapsulated structure containing two copies of a single-stranded RNA genome. It adsorbs onto the surface of a cell by means of an interaction between its envelope glycoprotein and its cellular receptor, and so enters the cell by means of receptor-mediated endocytosis. Inside the cell, the vial RNA is reverse transcribed by a series of steps into linear double-stranded DNA, and this form of the virus integrates into the host cell chromosomal DNA at an apparently random site. Once integrated, the viral genome is transcribed and translated using the cell's normal machinery. In a wild-type virus, the life cycle is completed by the combination of retroviral genomic RNA and proteins to assemble new viral particles that bud from the surface of the cell. In retroviral vectors of the type used for cell lineage marking, however, the life cycle is blocked at this point and new particles cannot be formed.

cause the two daughters of a stem cell can have quite different fates (Figure 7-2B, C). One daughter will become a stem cell similar to the mother cell. If this cell inherits the provirus, then the lineage will be simply be labeled one cell cycle later than was anticipated, just as for a symmetrically dividing lineage (Figure 7-2B). The other daughter cell, however, is likely to be a committed cell of some type, either an intermediate glial precursor cell, or (in the ultimate case) a postmitotic neuron. If this cell inherits the virus, the labeled clone of cells will be restricted in their fate, perhaps limited to a single neuron (Figure 7-2C). This restricted outcome will be the result of approximately 50% of infections of asymmetrically dividing stem cells. This presumably explains why so many one-cell neuronal clones have been observed in retroviral lineage experiments (Price and Thurlow, 1988; Walsh and Cepko, 1988; Moore and Price, 1992). This twist is quite fortuitous in that it helps to distinguish symmetric from asymmetric modes of division, but it complicates the interpretation of lineage data in that undetermined precursor cells can generate clones that appear restricted.

Returning to the life cycle of a wild-type retrovirus (Figure 7-1), the final step is the assembly of the viral proteins together with viral RNA to generate new viral particles, which bud from the cell surface. The retroviral vectors that are used as lineage labels, however, do not have this facility. They can infect cells, integrate, and express, but they have been engineered so that they cannot produce the next generation of viral particles. The life cycle is blocked at the stage indicated in Figure 7-1. This is of obvious importance if vectors are to be used as lineage labels. It would be useless if a virus used to mark a cell and its progeny were to spread the genetic label to neighboring cells. There would be no way to distinguish the progeny of the original cell from those secondarily infected. The lineage vectors have the added advantage that they encode genes that can be recognized histochemically. The *lacZ* gene encoding the enzyme β-galactosidase has been a favorite (Sanes et al., 1986; Price et al., 1987), although vectors encoding the alkaline phosphatase gene look set to become popular in the future (Fields-Berry et al., 1992).

The viral vectors that have been used for lineage studies fall into three categories: ecotropic mouse viruses, amphotropic mouse viruses, and chick viruses (see Stoker (1993) for a comprehensive list). The principle difference between them is their host range. Ecotropic mouse viruses, mostly based on Moloney murine leukemia virus (MLV), infect cells of mouse and rat but few other species. Amphotropic viruses carry the same range of genomes, but have a different coat protein, which allows them to infect a broader range of species, including chicks, rabbits, primates (including human) as well as rodents. The chick viruses that have been used for cell lineage studies are derived from the Rous sarcoma virus (RSV).

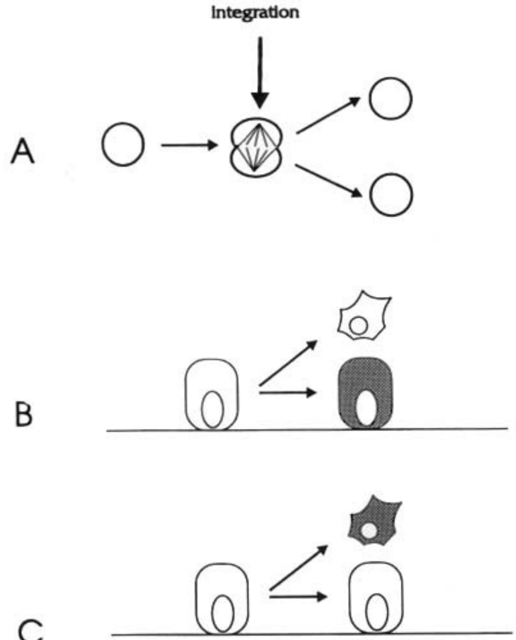

FIG. 7-2. Retroviral integration. (A) Although, as far as we are aware, a virus can infect a cell during any phase of the cell cycle, the process of integration only takes place as the cell divides. Thus the genetic labeling only occurs at this point. It follows, therefore, that when a cell is infected, only one of its daughter cells will actually inherit the genetic label. If the lineage is a symmetric one such as that shown here, in which both daughters are alike, then the effect of this delay in labeling is quantitative rather than qualitative. Effectively, the lineage is labeled one cell cycle later than might have been thought to be the case. (B, C) The consequence for an asymmetrically dividing precursor cell. This cell divides to give one daughter that is a stem cell the parent cell, and a second daughter that takes on a specific fate. In the context of the nervous system, this latter cell could be a post-mitotic neuron or a glial cell (or glial cell precursors), which will continue to divide, but only to give other glial cells. If, by chance, the stem cell daughter inherits the label (Figure B), then the lineage is labeled, just as with the symmetrically dividing precursor cell in Figure A. If the other daughter inherits the viral DNA, however, (Figure C) then the labeled clone is composed only of the differentiated progeny, which could be a single cell. Thus roughly 50% of stem cell infections will label restricted progeny, even though the originally infected stem cell might have a broad developmental potential.

Retroviruses avoid a number of the problems associated with injected lineage labels. They need not be injected directly into cells so the size of the cell becomes irrelevant and there is no danger of injection damage. They are known not to have any toxic effects on the infected cells, although this cannot be assumed for any novel gene they might be engineered to carry. They need only be introduced into the vicinity of dividing cells for the cells to become infected, so problems of inaccessibility of precursor cells are reduced. Most significantly, the genetic label never gets diluted however large the clone derived from the infected cell becomes.

Unfortunately, there are also disadvantages. One problem is that, although the marker gene will be inherited genetically, it will only be detected if it is expressed. If for any reason a cell were to turn off expression, it would disappear from the analysis. The extent to which this theoretical problem is of practical significance is still unclear; the endogenous enhancer of MLV is inactive in all cells of the preimplantation mouse embryo, and in undifferentiated embryonic stem cell lines (Jaenisch et al., 1975). From about 10 days of gestation, however, cells of all germ layers express genes driven by this enhancer (Savatier et al., 1990), and, although some cell lines do not express in a predictable way, the evidence for normal cells suggests reliable long-term expression for the most part.

The main disadvantage of the retroviral method, however, is that it has neither of the two principal certainties of the injection method: the experimenter knows neither precisely how many cells were infected, nor exactly where they were. Both of these have to be inferred in the final analysis from the distribution of labeled cells. This can lead to two types of error, which Walsh and Cepko (1992) call "lumping" or "splitting." If two closely neighboring cells became infected, two labeled clones would inhabit overlapping territory and so be "lumped" together as one. Alternatively, a labeled clone could generate a migratory cell that left the site of infection and generated a second cluster of labeled cells some distance from the main body of labeled cells. Because these two halves of the clone had become split, they might be mistakenly interpreted as being two distinct clones. As we shall see later, these are real problems in the interpretation of retroviral lineage data, for which there are as yet no easy solutions. What is required is an unequivocal means of distinguishing clones. So far, the only proposed solution to this problem has come from Walsh and Cepko (1992). Their method uses 100 different viral variants that can be distinguished by polymerase chain reaction, and this they have applied to the study of cell lineage in the cerebral cortex (see below). Whether this will provide the ultimate solution to the errors of interpretation, however, is not clear. The polymerase chain reaction method has its own problems of interpretation, as has been discussed elsewhere (Kirkwood et al., 1992), but equally significantly, this method is far from simple. Generating so many different viruses is a considerable amount of labor, especially as each virus has to be of precisely equal titer. This may limit the extensive adoption of the technique. Currently, several laboratories are study-

ing glial cell lineage, successfully working within the limitations of the original technique, but the Walsh and Cepko method, or something like it, is certainly required if retroviral lineage labeling is to fulfil its full potential.

These problems notwithstanding, with the retroviral technique we have the potential to label almost any precursor cell in the embryo by injecting virus into its vicinity (see Price, 1993a for a practical guide). Once labeled, the cell can be left for as little time as 2 days (the minimum required for expression of the virus) or as long as the lifetime of the animal before the infected tissue is analyzed to discover what has become of the labeled cell. This approach has now been applied to the retina (Sun and Wekerle, 1986; Turner and Cepko, 1987), cerebral cortex (Luskin et al., 1988; Price and Thurlow, 1988; Walsh and Cepko, 1988, 1992; Austin and Cepko, 1990; Grove et al., 1993), hippocampus (Grove et al., 1992a) and striatum (Halliday and Cepko, 1992) of rodents, and the optic tectum (Gray et al., 1988; Galileo et al., 1990; Gray and Sanes, 1991; Johnston and Van der Kooy, 1992), spinal cord (Leber et al., 1990), and neural crest (Frank and Sanes, 1991) of birds.

OTHER METHODS OF FOLLOWING CELL FATE

These two methods—the injection of lineage tracers, and retroviral vectors—have been the two most prominent methods for studying cell lineage in vertebrates over the past decade. The study of fate determination in general, however, has involved a number of other types of study. Before we consider those, we need to consider how different approaches relate to each other conceptually.

The study of cell lineage is the study of presumptive fate. By labeling a precursor cell *in vivo*, we discover what it will generate if left undisturbed. A different experiment would be to label the cell, then move it to a different environment—another part of the embryo for example, or into a tissue culture dish. In the new environment, it might behave differently. We can imagine circumstances under which it might show either a greater or a lesser potential than it would have shown undisturbed. For example, a precursor cell might have the potential to generate, say, both astrocytes and oligodendrocytes, but only one cell type might arise *in vivo* because to generate the other, the cell must be stimulated by a particular factor. The factor might be missing from the cell's natural environment, but present in the alternative environment. Conversely, the factor might be present in the natural environment so that the precursor cell generates both oligodendrocytes and astrocytes, but absent from the new environment. Therefore cell lineage—the study of the undisturbed cell—does not necessarily tell us the cell's full potential, whereas following a cell in a foreign environment, tells us something of its developmental potential without telling us the cell's presumptive fate.

In parallel with the distinction between presumptive fate and developmental potential, we also need to observe that between studies of single cells and cell populations. Just as a single cell can be labeled and its fate followed, so a population of cells can be labeled and their collective fate recorded. A study of the presumptive fate of cells is termed a *fate map,* a description of the contribution made by populations of cells in the embryo to the final adult structure. This is analogous to the study of cell lineage, but fails to address the questions we set ourselves earlier because it does not tell us what individual cells are doing. We know that if we labeled neuroepithelial cells as a population, they would give rise to neurons and glia. The question is: Are individual cells generating all the cell types, or just some of them?

STUDIES OF CELL POPULATIONS

As with lineage studies, the principal problem in studying cell populations is how to label them. For many years embryologists were limited to those cells that fortuitously carried natural markers, such as yolk granules or pigments, or that could easily be labeled with vital dyes such as neutral red. Currently, however, there are a wide variety of labeling techniques available. Several can be applied to normal *in vivo* development, and many others can be used to distinguish cells that have been transplanted into an alternative environment.

Labeling Populations In Vivo

The problem with techniques for labeling normal cells *in vivo* is that they generally give the experimenter little control over the precise population to be labeled. Three examples that are otherwise very different are fluorescent labels, rodent chimeras, and nucleotide labels, such as thymidine (TdR) and bromodeoxyuridine (BrdU).

Fluorescent Labels. Labeling individual cells by the injection of dye substances has already been described. Populations can also be labeled without the necessity for individual cells to be injected. Fluorescent labels such as CFSE (Bronner-Fraser, 1985) or the carbocyanine dyes (Honig and Hume, 1986;

Godeman et al., 1987) label cells by passive uptake or incorporation into the cell membrane, respectively. The carbocyanine dyes have revolutionized the tracing of axonal pathways, but have also been useful in labeling radial glial cells. In particular, this has led to the best evidence to date that radial glia give rise to protoplasmic astrocytes (Voight, 1989).

Rodent Chimeras. There are a variety of ways of generating chimeras—individuals whose cells are a mixture of two different genotypes. The most common in studies of brain development is to aggregate morulae from two different mouse strains to give an apparently normal individual, made up of cells from both strains (Herrup et al., 1984; Herrup and Sunter, 1986; Goldowitz, 1987, 1989; R. Williams and Goldowitz, 1992b). The proportion from each strain varies between individuals and depends primarily on the proportion of cells from each morula that happened to contribute to the embryo rather than to the extraembryonic tissues. The two strains are selected because their cells can be distinguished histochemically. Thus, by staining sections of brain, the contribution made by each strain to any particular brain structure can be determined.

The problem with this approach has always been one of interpretation. Since the strains were combined so early in development, both contribute to all parts of the embryo, but there are local distortions in both the proportions and distributions of the cells derived from each strain. These distortions have been translated into counts of the number of founder cells of different areas (Herrup et al., 1984; Herrup and Sunter, 1986), and into evidence for developmental compartments (Crandall and Herrup, 1990; R. Williams and Goldowitz, 1992b). These interpretations have been criticised on methodological grounds (Mead et al., 1987; Jennings, 1988). They also tend to ignore artifacts such as the apparent tendency of cells of different strains to differentially adhere (Goldowitz, 1989).

These limitations notwithstanding, chimeras have proved a useful way of following the fate of glial cells, particularly in the study of microglia. By taking bone marrow from one rodent strain and transferring into an irradiated host of another strain, for example, experimenters have been able to address the question of whether microglia cell populations were derived from host or grafted tissue (Lassmann et al. 1993). This relates to the issue of origin of microglial cells, discussed in Chapter 10.

Nucleotide Labeling. The labeling of cells with TdR has a much more established pedigree. If TdR (or, more recently, BrdU) is introduced into an embryo, it is taken up by all the dividing cells, which incorporate it into their nascent DNA and pass it on to their progeny. Cells that continue to divide dilute out the labeled TdR at each subsequent S phase, but cells that become labeled immediately before their final division carry the radiolabel into adulthood. This has been an immensely important technique for establishing the timing of production of different cell types, particularly neurons, but also glial cells such as those of the optic nerve (Skoff et al., 1976a, 1976b; Skoff, 1990). It has also provided a means of labeling cells for transplantation so that they can be distinguished from host cells (Lindsay and Raisman, 1984).

Nucleotide labels are not good lineage labels because they label all dividing precursor cells indiscriminately, and therefore provide no means of distinguishing the progeny of different cells. This does not mean that studies of populations of cells labeled in this way cannot be extremely informative. A good example is the study of Watanabe and Raff (1988), who showed that retinal astrocytes are derived from the optic nerve rather than being indigenous retinal cells. In part, this conclusion was derived from experiments in which retinal populations from different developmental stages were cultured together. By first labeling one population with BrdU, Watanabe and Raff were able to distinguish between the progeny of the different populations. Like the study of Espinosa de los Monteros et al. (1993) discussed below, this is good example of how single-cell labeling need not be necessary in studying fate if all the members of a population behave similarly with regard to the particular feature being studied. As we shall see later in our discussion of retinal lineage, the Watanabe and Raff result complemented the retroviral lineage data nicely to give a more complete picture of retinal lineage.

Labeling Transplanted Cells

In considering cell transplantation, we are straying rather far from our subject of cell lineage. Not only are we considering the development of cell populations rather than single cells, we are also considering cells whose development has been perturbed by transplantation. Nonetheless, much of what we know of cell fate comes from such studies, and in many cases they have been immensely informative. Perhaps the single most significant in this regard is the chick-quail chimera system.

The Chick-Quail System. First described by Le Douarin, chick-quail chimeras have proved to be probably the most successful approach to cell label-

ing in modern embryology (see Le Douarin, 1982). The basis of the technique is that chick and quail cells can be distinguished by the appearance of their nuclei after Feulgen staining. This means that cells transplanted from one species into the other can be distinguished from the indigenous cells. Thus a piece of neuroepithelium, for example, can be transplanted from a quail embryo into the equivalent site of a chick at the same embryonic stage. After the animal has developed, the contribution of the transplant to the developed structure can be determined. The result of such an isochronic, isotopic transplant is not strictly a fate map because cells have not been labeled undisturbed, but transplanted between embryos. But because exactly equivalent cells have been transplanted, they are assumed to develop exactly as the undisturbed cells would have done, and the result is considered to be a fate map.

Heterotopic and heterochronic grafts are also possible; that is, cells can be transplanted to inappropriate positions in the embryo, and between embryos at different developmental stages. Thus, this versatile approach can give information about the developmental potential of cells, as well as their presumptive fate. As a consequence, we know a great deal about the fate of the avian neural crest (including peripheral glial cells) particularly from the work of Le Douarin. The approach is being turned increasingly to the central nervous system to generate fate maps of the avian neural plate, and to address questions regarding the positional specification of the neural plate.

This technique has told us a considerable amount about the derivation of peripheral nervous system glia. All peripheral nervous system glia are derived from the neural crest (Le Douarin et al., 1991). This includes satellite cells, both myelinating and nonmyelinating Schwann cells, and the cells of some cutaneous receptors (Halata et al., 1990). The only exception is the sheath cells of the ventral root, which have been observed (also using chick-quail chimeras) to arise directly from the ventral neural tube (Lunn et al., 1987). Some workers, however, doubt this observation (Le Douarin et al., 1991). Little has been done specifically on central nervous system glia using this technique, although some observations have been made in passing. For example, Hallonet et al. (1990) have suggested that the glial cells of the avian cerebellum are derived directly from the neuroepithelium, not from the external granular layer.

Other Labeling Techniques for Transplanted Cells. There have been too many different approaches to labeling cells for transplantation for them all to be considered in detail here, especially since most are not specifically concerned with following cell fate. Some of the methods that have already been mentioned have also been used to label cells for transplantation, for example, retroviruses (Emson et al., 1990) and thymidine (McConnell, 1985, 1988; Emmett et al., 1991). Astrocytes have been labeled with fluorescent beads to aid their recognition following transplantation (Emmett et al., 1991). O-2A cells have been labeled with the fluorescent dye, fast blue (Espinosa de los Monteros et al., 1993).

A technique that has been prominent in glial cell biology has been to transplant pieces of tissue either from mutant animals into wild type, or vice versa (Duncan et al., 1988; Rosenbluth et al., 1990; Gansmuller et al., 1991). A number of mutants, such as the *shiverer* mouse and the myelin-deficient rat, are deficient in oligodendrocytes. Thus either explants of normal tissue (or isolated oligodendrocytes or Schwann cells from normal animals) are easily recognized following transplantation into mutant hosts, since they are the only source of myelinating cells. Conceptually similar is the approach of Blakemore and his colleagues in which a region of spinal cord is experimentally demyelinated then used as a target tissue for the implantation of glial cells (Blakemore and Franklin, 1991).

Most of these studies of oligodendrocytes have primarily addressed the process of myelination, rather that the process of cell fate allocation *per se*. An exception is the study of Espinosa de los Monteros and colleagues (1993) where cultured O-2A cells were labeled with the dye, fast blue, and transplanted into neonatal brain to see whether they generated astrocytes or oligodendrocytes. O-2A cells generate both cell types in tissue culture, but evidence that they produce astrocytes *in vivo* has been lacking (see Chapter 8 for a discussion of this issue). Since the transplanted cells generated oligodendrocytes but not astrocytes, this was taken as support for the contention that the O-2A cell is primarily an oligodendrocyte precursor cell *in vivo*.

Note that in this study, the transplanted cells are cultured cells, operationally defined as all belonging to the same type. Had the result been that the transplanted cells also generated astrocytes, the question would have arisen whether contaminating astroblasts could have contributed that cell type, or whether all the defined cells were really identical in developmental terms. In the event, that consideration was unnecessary, but we see how the conclusions from this study differ inherently from those that follow from single-cell, cell lineage studies. Similarly, the cells in question were derived from neonatal animals, cultured for approximately 2 weeks

in total. This is therefore a heterochronic graft, which limits the conclusions that can be drawn about the fate of undisturbed neonatal O-2A cells. These considerations highlight nicely the contrast between a study of single undisturbed cells and transplanted populations.

Finally, in this section we should consider the transplantation of cell lines. Primary cells taken from embryonic brain usually have a finite lifetime *in vitro*. An oncogene, however, can immortalize precursor cells, that is, induce them to divide *in vitro* for considerably extended periods. This allows time for individual precursor cells to expand into clones of many millions of cells, which can be labeled with retrovirus and transplanted into a normally developing central nervous system (Renfranz et al., 1991; Snyder et al., 1992). Since the transplanted cells were derived from a single transformed precursor cell, all the progeny of the transplanted cells are clonally related. As such, they represent the developmental potential of the founder cell. The question that is begged, of course, is how this potential is related to that the cell possessed before it was transformed.

A second question is how typically this potential of the transformed cell reflects the true potential of a cell *in vivo*, and if it does, then how representative this is of the starting population of precursor cells. Only a tiny proportion of cells become immortalized by the oncogene, and there is no reason to believe that all precursor cells have an equal tendency to become immortalized. So, in addition to the proviso of all transplantation studies regarding the relationship between presumptive fate and developmental potential, with cell lines there is the doubt that the developmental potential is a genuine one.

The true value of cell lines lies not in cell lineage, for which they are a poor substitute, but in the broader issue of fate determination. Consider the study of Renfranz et al. (1991). They immortalized a cell line derived from rat hippocampus and injected the cells into, among other sites, the cerebellum. There the cells gave rise to granule cells and Bergmann glia. This is a remarkable finding, which potentially has great significance for the therapeutic application of cell transplantation, especially since there seems no reason to believe that the cells generated were not genuine, functional granule cells and Bergmann glia. But what of cell lineage? The study of Hallonet et al. (1990) suggest that, in avian species, granule cells and Bergmann glia are derived from different areas of the neuroepithelium. Assuming the same to be true of rodents, we can conclude that no normal neural precursor cell ever expresses the potential demonstrated by this cell line. The juxtaposition of these studies of cell lineage and cell transplantation have, therefore, highlighted an important set of questions. Either neural precursor cells (or at least some of them) have a considerably broader potential than they will ever express—a potential that even crosses the major neuromeric divisions of the brain—or the process of immortalization has induced a primitive neurogenic fate, never found *in vivo*. If we could settle between these alternatives, we would be a good deal closer to understanding fate determination in the nervous system.

Means of Studying the Progress of Differentiation

There are other means of studying populations of cells that, though not studies of cell lineage *per se*, provide relevant information, and are indeed often confused with studies of lineage. The study of cell differentiation is a particularly important example. As cells differentiate, they synthesize specific macromolecules that can be considered markers of that differentiated state. Glial fibrillary acidic protein, for instance, is specifically made by astrocytes in the central nervous system, and is a marker of that cell type. A related set of intermediate filament proteins, neurofilaments, are likewise specific for neurons. Two obvious developmental questions arise: when in ontogeny is each marker first expressed; and what is the sequence in which markers of a cell type begin to be expressed?

These questions lead us to a description of the process of differentiation, and as such have proved very useful in the study of many cell types, including glia. Such studies do not, however, say anything directly about cell lineage, or the timing of commitment, although they may allow such conclusions to be inferred indirectly. For instance, many markers first appear in precursor cells. The temptation is to assume that these differentiation markers are also markers of lineage; to assume that is, that a marked population of precursor cells is restricted to the production of the cell type in question, and that this restriction of developmental potential occurred at the time of appearance of the marker. Neither of these conclusions can be defended logically. Restriction of gene expression in precursor cells, which presumably underlies the appearance of the marker, might be quite different from restriction in mature cells. So it proves with the markers I have mentioned. Both glial fibrillary acidic protein and neurofilaments are found in some neuroepithelial cells (Levitt et al., 1981; Tapscott et al., 1981; Bennett and DiLullo, 1985). Since this expression is only in some cells, this certainly tells us that there is hetero-

geneity among these precursor cells, and that is important in adjudicating between our various lineage models. Nonetheless, this observation has not told us what these cells will become, and the danger of believing the contrary becomes apparent when we consider that these markers are known to be expressed by cells that take on a different fate. Some embryonic heart cells, for example, express neurofilaments (Bennett and DiLullo, 1985); some young oligodendrocytes express glial fibrillary acidic protein (Choi and Kim, 1984; Ogawa et al., 1985). The important point is that tracing the appearance of markers in differentiating cells tells us something about the process of differentiation; but the appearance of markers in dividing cells does not reveal when lineages diverge nor when cell fate decisions are made.

Markers of differentiation are nonetheless very useful tools so long as these traps of interpretation are avoided. They can be particularly useful in defining populations of cells. A good example is the monoclonal antibody A2B5 and its role in defining the O-2A cell. A2B5 is not monospecific in as much as it recognizes glycosylation groups found on a number of proteins and lipids. Nonetheless, among neonatal rat optic nerve cells it recognizes a population of cells, which can become either oligodendrocytes or astrocytes in culture, depending on the conditions (Raff et al., 1983; see Chapter 8, this volume). Because almost all of this population could take on either fate, each cell must have been bipotential, regardless of the heterogeneity of the molecules recognized by the antibody, or of the subsequent expression pattern of these antigenic determinants. This conclusion was crucial in defining the potential of the O-2A cell in culture (Raff, 1989).

Studying Fate in Tissue Culture

Overwhelmingly, the most convenient means of studying developmental potential is in tissue culture. There is an almost infinite variation of types of cultures now available for the study of glial cells, and each have their relative advantages and disadvantages. All, however, have a number of advantages over studying cells *in vivo*. Cells in culture are more accessible, and more manipulable. They can be transferred from one environment to another; they can be injected; they can be sorted with a cell sorter; they can be photographed with a time-lapse camera. All of these are more difficult *in vivo*. Most importantly, the environment of a cell can be controlled in culture in a fashion that is impossible *in vivo*. Cells can be grown on different substrates, in the presence of different growth factors or drugs, alone or with other cells.

Different culture systems trade some of these advantages for verisimilitude. In slice and reaggregate cultures, cells retain some of their normal histotypic relationships, whereas in dissociated cultures, all such relationships are assumed to be lost. The ultimate is single-cell culture; the cell's environment is completely controlled but completely artificial.

Cell Labeling in Tissue Culture

Even in culture, the central problem of cell lineage studies remains: how can the fate of single cells be analyzed in the presence of many other cells? In general, the methods that have already been discussed in relation to *in vivo* experiments are also available for tissue culture studies, plus others that are only applicable to tissue culture. I know of no studies in which lineage labels have been injected into glial precursor cells in culture, but retroviruses are beginning to be applied to tissue culture studies. They have shown that in the embryonic cerebral cortex, separate precursor cells generate each different cell type, and that a further precursor type generates both neurons and oligodendrocytes (B. Williams et al., 1991). They have shown oligodendrocyte and astrocyte precursors to be separate in the neonatal cortex (Vaysse and Goldman, 1990), and multiple astrocyte precursor types in the neonatal spinal cord (Miller and Szigeti, 1991). In addition, many of the means of labeling cell populations have been applied to tissue culture studies. We have already seen how, for example, Watanabe and Raff (1988) used BrdU to label glial precursors in their study of cell fate in the retina.

There are, however, two means of following fate that are restricted almost exclusively to tissue culture. First, cells can be followed by direct observation. Second, cells can be cultured as individual cells so that their fate can be observed in total isolation from cell-cell contact.

The direct observation of developing cells is not impossible *in vivo*, but it is largely restricted to invertebrates and those rare vertebrates, such as zebrafish, whose embryos are small and transparent (Kimmel and Warga, 1988). In low-density culture, however, either with or without marker substances, cells can be directly observed with ease, especially with the aid of time-lapse microscopy. There are multiple examples of this in glial cell biology. The parameters that can be determined in this way include changes in morphological differentiation (Dubois-

Dalcq, 1987; Wolswijk and Noble, 1992), and rates and degree of symmetry of division (Wolswijk and Noble, 1989). Thus aspects of a cell's fate can be observed directly.

The culture of single cells is, in a sense, the ultimate cell fate experiment. In the absence of neighboring cells, the cell's environment is as isolated and controlled as can be achieved experimentally. As we have already discussed, such an experiment will tell us something of a cell's developmental potential. In particular, the cell's constitutive pathway of development is revealed (not necessarily the same as its presumptive fate); that is, the fate the cell will assume in the absence of any further environmental influence. The O-2A cell provides a good example of this: grown alone in the absence of any factors except those required to keep the cell alive and dividing, O-2A cells generate oligodendrocytes (Temple and Raff, 1985, 1986). This, therefore, is considered to be the constitutive pathway of O-2A development (Raff, 1989). In this case, this is probably also this cell's presumptive fate. Most of the current data available suggests that O-2A cells generate predominantly (possibly exclusively) oligodendrocytes *in vivo* (for reviews see Raff, 1989; Goldman and Vaysse, 1991; B. Williams and Price, 1992).

It is clear from the foregoing discussion that there is in a sense a compromise in all studies of cell fate. At one extreme is the study of cell lineage. This is unique in that a cell only has one presumptive fate, and that is what the study of cell lineage reveals. There is a purity to such a study, but its interpretation is often difficult. Do cells take on different presumptive fates because of intrinsic differences in developmental potential, or because of environmental differences? Answers to such questions are seldom forthcoming from cell lineage studies. Questions of developmental potential require experimental interference, and two elements of compromise immediately arise: first, are cell populations, which are easier to study, representative of the single cells of which they are composed; second, how normal does a cell have to be, and how normal does its environment have to be to give results that are relevant to the *in vivo* situation, yet sufficiently simplified to be under experimental control? Such considerations are complex, and each experimental situation has to be considered on its own merits. The central position of cell lineage in this discussion is that it provides the control for the interpretation of experimental investigations. Cell lineage information is, therefore, indispensable in understanding the process of cell fate allocation, but seldom sufficient in itself.

CASE STUDIES: A COMPARISON OF RETINA AND CEREBRAL CORTEX

In this chapter, I have discussed the sorts of approaches that have been applied to studies of cell fate, the types of data these approaches provide, and how these bodies of data relate to each other conceptually. Let us consider finally the answers that have resulted from the application of combinations of these approaches to the study of central nervous system development using as examples the retina and cerebral cortex. These examples are useful, first, because we have a reasonable grasp of the lineage relationships in both cases, but also because the patterns of cell lineage in each case look quite different.

Cell lineage in the retina has been extensively studied using retroviruses in rodents (Sun and Wekerle, 1986; Turner and Cepko, 1987), and by label injection in amphibians (Holt et al., 1988; Wetts and Fraser, 1988). These different data concur substantially: precursor cells labeled throughout the period of retinal development tend to be composed of multiple cell types. Even if precursor cells are labeled just prior to their final or penultimate division such that clones of between one and four cells predominate, these clones are often composed of multiple types. This indicates that retinal precursor cells are multipotential and suggests that they retain their multipotency as long as they continue to divide (Figure 7-3). This final conclusion has been questioned on the grounds that mixed clones occur less frequently than would be expected from such precursor cells if their fate were determined purely stochastically (R. Williams and Goldowitz, 1992a), but even so the multipotential model probably fits the data best (Price, 1993b).

The only exception to the above finding was the retinal astrocytes. This cell type was not included in the clones composed of the other retinal cell types. Müller glial cells, on the other hand, were included in these retinal clones (Figure 7-3B). Thus Müller cells are derived from the same population of precursor cells that generate the retinal photoreceptors and neurons, but the astrocytes are not. As we have already seen, this is consistent with culture data that suggest that the astrocytes are derived from progenitor cells that migrate into the retina from the optic nerve (Watanabe and Raff, 1988). Oligodendrocytes do not come into the equation at least in rodents because their retinas do not have this cell type. We have as yet no lineage information from species, such as the rabbit, that have retinal oligodendrocytes, but there is indirect evidence that, like astrocytes, these cells migrate into the retina (Schnitzer, 1985; ffrench-Constant et al., 1988).

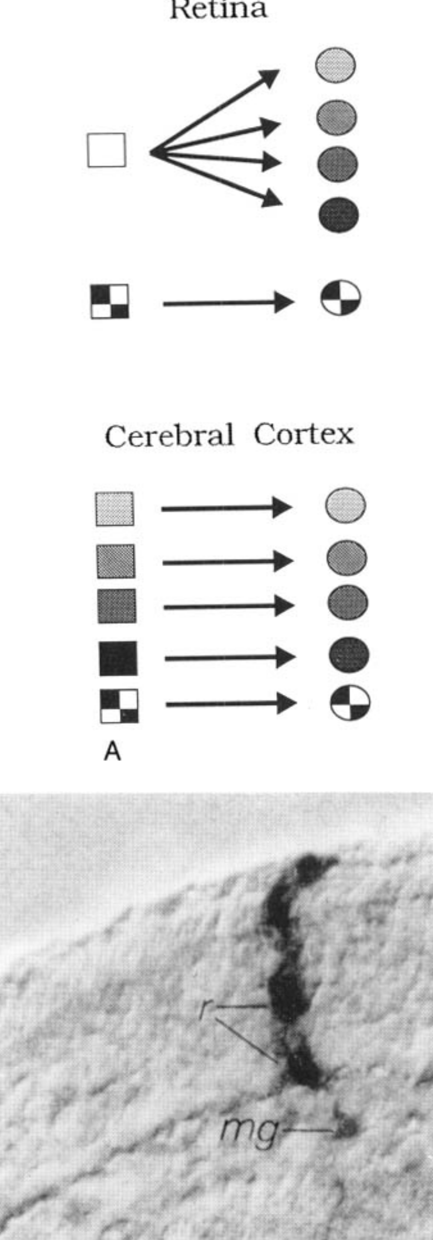

FIG. 7-3. (A) Lineage models in retina and cerebral cortex. The shaded ovals represent differentiated cells of different types. The rectangles represent their precursor cells. In the retina, a variety of different cell types are derived from a multipotential precursor cell (*unshaded rectangle*). Astrocytes (the chequered oval), however, are derived from a separate precursor cell population. In the cortex, each cell type seems to have its own precursor cell population. (B) Retinal Müller glia are derived from the same precursor cells as the retinal neurons and photoreceptors. The photomicrograph shows a retrovirally labeled clone in the retina. It is made up of a number of rod photoreceptors (*r*) and a Müller glial cell (*mg*). [From Turner and Cepko (1987), with permission.]

In the cerebral cortex, the picture looks very different (Figure 7-4). Studies with retroviral vectors in the rat embryo give clones that are composed almost entirely of a single cell type (Luskin et al., 1988; Price and Thurlow, 1988; Grove et al., 1993). Three, possibly four, of these are glial: there are distinct clones of gray matter astrocytes, white matter astrocytes, oligodendrocytes, and a fourth type of cell that appears astrocytic but does not contain glial fibrillary acidic protein (Grove et al., 1993). In addition, there are probably two types of neuronal clone (Parnavelas et al., 1992). So unlike the retina where precursor cells are multipotential, in the cortex they appear, at least by the time neurogenesis has commenced, to have become dedicated to the production to a single cell type.

There are probably some exceptions to this general rule. Several investigators have reported clones that are composed of multiple cell types (Price and Thurlow, 1988; Grove et al., 1993; Walsh and Cepko, 1992), but although all the data are not entirely consistent such clones appear at present to be relatively rare. More clearly demonstrated is a precursor cell, observed both *in vivo* and in cultures of cortical cells, that generates both neurons and oligodendrocytes (B. Williams et al., 1991). The significance of a cell with this slightly odd bipotentiality is not yet clear, but clones with mixed cell types probably represent multipotential precursor cells remaining from earlier developmental stages when, presumably, they were predominant. There are as yet no data on such early cortical precursor cells, although the forebrain, both in the embryo (Temple, 1989) and the adult (Reynolds et al., 1992) does seem to include precursor cells with the capacity to generate neurons and astrocytes in culture. Some cell lines derived from the embryonic forebrain show a similar potential when transplanted ectopically (Renfranz et al., 1991; Snyder et al., 1992). It is not clear why cells that generate this combination have not yet been found *in vivo*, but any of the reasons already discussed could explain the discrepancy. Also, it is possible that the lineage experiments, which are still incomplete, could have missed such clones.

There is a complication associated with these cortical data that does not apply to the retinal results. As already noted, a disadvantage with the retroviral approach is that the exact number and position of the infected cells is not known with certainty. Thus, if clones were to disperse too freely, there would be a possibility either that separate labeled clones could become superimposed so as to resemble a single clone, or that one clone could split into two halves, each of which were taken for a complete clone (Walsh and Cepko, 1992). Needless to say, either eventuality could confuse the lineage picture that emerged. In the retina, clones disperse to a very limited extent (Turner and Cepko, 1987), a finding that has been confirmed by the analysis of rodent chimeras (Goldowitz, 1989). In the cortex, however, the suggestion is that dispersion is considerable (Walsh and Cepko, 1988, 1992). Since the great majority of clones appear to have a single cell type, it is unlikely that they are becoming superimposed since this would tend to generate mixes. However, the possibility that two apparent clones could be one clone split in two must be considered.

The data *in vivo* are not yet sufficiently complete to resolve this issue, but studies in tissue culture suggest that the splitting of clones is not sufficient to

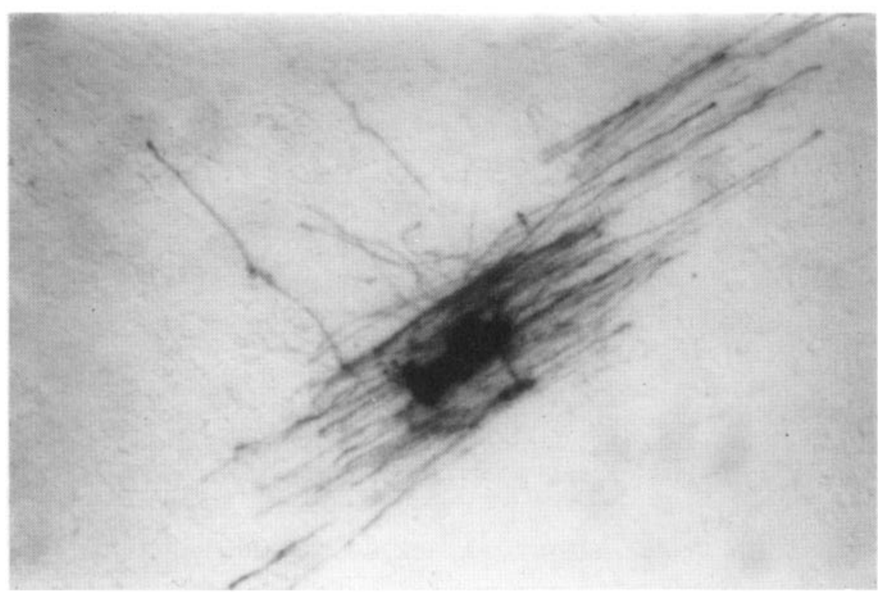

FIG. 7-4. A clone of oligodendrocytes in the external capsule. The precursor cell that gave rise to this cluster of oligodendrocytes was labeled by injecting a retrovirus into the cerebral vesicle at embryonic day 16 in the rat embryo as described in Grove et al. (1993).

distort the data appreciably. When cortical cells are labeled with virus and grown in culture, each clone only generates a single cell type, as *in vivo* (B. Williams et al., 1991). The exception is the neuron-oligodendrocyte combination already noted. The difference between studies of cells in culture and *in vivo* has been dwelt on sufficiently in this chapter with being repeated here. Nonetheless, the similarity between the two results suggests that if clones *in vivo* are being artefactually split into two parts, then both parts are probably composed of the same cell type.

The contrast between glial lineages in the retina and the cerebral cortex, therefore, could not be starker (Figure 7-3). In the former, there are no indigenous glial precursor cells as such; the only native glial cell, the Müller cell, comes from a multipotential precursor cell. In the cortex, there are at least three populations of dedicated glial precursor cells during the embryonic period, plus the N-O cell. The significance of cell lineage studies in defining questions in glial cell development could not be more dramatically outlined than by this comparison.

The challenges for the future lead in a number of directions. For those regions where the lineage pattern is becoming clear, the problem now is mechanism. In the retina, what determines the fate of the multipotential precursor cell? This question has both cellular and molecular aspects. Presumably cells influence each other in bringing about fate decisions. Indeed there is already evidence for such interactions (Reh and Tully, 1986; Watanabe and Raff, 1990). We also need to understand the factors that mediate such interactions, and how they work to change cell behavior (Anchan et al., 1991; Watanabe and Raff, 1992). In the cortex, we can ask what makes the different precursor cell types different, and what controls the behavior of each precursor. Fate determination, however, is still a problem in the cortex, since we have yet to discover when and in which cells fate becomes determined. The problem is that the cell lineage data is still incomplete.

In other regions, the study has yet to be begun. One of the intriguing questions is whether the retinal or cortical patterns of lineage will turn out to be the more typical. Currently, the retinal pattern seems to have the edge in that multipotential precursor cells seem to predominate in the optic tectum (Gray et al., 1988; Galileo et al., 1990; Gray and Sanes, 1992), the spinal cord (Leber et al., 1990), and the neural crest (Bronner-Fraser and Fraser, 1988, 1989) of the chick. On the other hand, the hindbrain seems to be composed of dedicated precursor cells from very early stages (Fraser et al., 1990). Since most of these studies have been on early chick embryos, much of glial lineage, which occurs later, is particularly obscure. Most of the questions surrounding glial cell lineage, however, now seem approachable. I would anticipate the next decade to be a very productive one in regard to this field of study.

I thank Dr. Brenda Williams for her helpful comments on this manuscript. My work described in this chapter was supported by the Medical Research Council, the Multiple Sclerosis Society of Great Britain and Northern Ireland, and the Commission of the European Communities.

8 The origins and lineages of macroglial cells

ROBERT P. SKOFF AND PAMELA E. KNAPP

The question whether astrocytes, oligodendrocytes, and microglial cells are distinct types of cells in the brain was resolved only after an 80-year controversy. The debate began in the mid-nineteenth century and lasted until the 1920s when Rio Hortega showed with his classical silver impregnation methods that microglia are distinct from oligodendrocytes (Rio Hortega, 1921). Today, the existence of these three separate types of central nervous system glial cells is universally accepted, but their lineages and origins are still unclear. The questions asked by modern neurobiologists about glial cell lineage are the same types of questions as those asked over a century ago. Histologists in the late nineteenth century grappled with the question of whether neurons and glia are derived from a common stem cell (reviewed in Jones, 1929; Jacobson, 1991). One view, proposed by His in 1887, is that the germinal zone is composed of two populations of precursor cells, one giving rise to neurons and the other to glia. The opposite view, put forth by Schaper and others in the 1890s, is that the cells in the germinal zone are multipotential, capable of giving rise to both neurons and glia. The two positions are still being debated and, even using the latest techniques such as retroviral tracing, evidence can be found to support either His' or Schaper's hypothesis. The origins of microglia are equally uncertain, with one theory in support of a mesenchymal origin, while another proposes a neuroectodermal origin. The two theories have traded popularity over the past 70 years. In the 1980s, for example, considerable evidence accumulated in favor of a mesenchymal-macrophage origin for all microglia, but evidence has accumulated in this decade to support a neuroectodermal origin for some microglia (e.g., DeGroot, 1992; Chapter 10, this volume). If some microglia do originate from neuroectoderm, when does this cell type split away from the macroglial lineage and what neural cells are they most closely related to?

The critical issue about the lineage of macroglial cells concerns whether astrocytes and oligodendrocytes are derived from a common precursor cell or whether they derive from separate precursors. This issue is the subject of the present chapter, and our discussion focuses on the origins of macroglia in pre- and postnatal development and the lineage of macroglia in postnatal development. We will define the *origin* of glia as the region of the ventricular zone where glial precursors are born in relation to their final destination in the brain (e.g., the precursors of oligodendrocytes in the spinal cord may originate exclusively from the ventral half of the ventricular zone of the neural tube) (Warf et al., 1991). We will consider *lineage* in this chapter in a fairly restrictive sense and use the term to refer solely to a cell's *developmental history* or to its *ancestry* in the central nervous system. Using this definition, cell lineage is much like tracing our own family ancestry. The lineage of a cell may be determined without knowledge of *how* and *when* environmental factors interact with intrinsic, genetic determinants. It is studied by determining the phenotype of the precursor cell and the phenotype(s) of all its daughter cells. It thus defines the *normal* derivation of a group of cells within the central nervous system, without consideration of the factors that influence the lineage pathway taken by individual cells. Cell lineage is but one aspect of a larger picture defining a cell's developmental fate and potential. The concept of cellular committment and the ability of cells to adopt alternative fates (Jacobson, 1991; Chapter 7, this volume) are all properties of a cell's development, which are, in most cases, deduced from experimental manipulation of the cell or of its surrounding environment.

IN VIVO STUDIES

Origins of Macroglia in the Brain

The ventricular cells that surround the cerebral ventricles, the spinal canal, the optic canal and the optic cup are the site of origin for all the neurons and glia in the central nervous system. The ventricular zone

is a single pseudostratified columnar layer whose cells, with time, will migrate out of it and populate the embryonic subventricular, intermediate, and marginal zones (The Boulder Committee, 1970). It has been generally assumed that each region of the ventricular zone is intermixed with progenitor cells capable of generating all the varieties of neurons and glia that are located in the adjacent gray and white matter of the adult nervous system. However, a number of recent studies suggests that the ventricular layer may be fate-restricted with regard to the types of cells it is capable of generating. These studies provide information not only about the origin of specific subtypes of glia in the brain, but they also reveal new properties of glia: they show glial progenitors may use unique migration routes to reach their destination and they provide information about the time of divergence of glial lineages. Most importantly, as additional information is obtained about fate-restricted zones, these studies should clarify neuronal and glial lineages by showing that cells in specific regions of the brain are capable of generating only one or more types of cells.

In the spinal cord, the origin of oligodendrocytes may be restricted to the ventral half of the ventricular layer (Warf et al., 1991). By culturing cells from either E14 ventral or dorsal segments of the cord, the investigators show that the ventral segments, but not the dorsal segments, have the potential to generate oligodendrocytes. The dorsal half does not exhibit this capacity until E16, strongly suggesting that the precursors of oligodendrocytes migrate from the ventral to the dorsal half of the cord. Using Dil to label cells in the ventral half of the cord, Warf and collaborators found galactocerebroside $(GC)^+$, Dil cells in the dorsal half within 18 hours. Presumably, after the oligodendrocyte precursors migrate to the dorsal half, they divide and populate the sensory half of the cord.

In the retina, it is well established that precursor cells in the retinal neuroepithelium give rise to the different types of neurons and to the Müller cells, a modified form of astrocyte (e.g., Wetts and Fraser, 1988). The origin of the astrocytes in the nerve fiber layer of the retina is less clear but several lines of evidence suggest that the astrocyte precursors migrate into the eye. Retroviral studies (Turner and Cepko, 1987) and tissue culture work suggests that astrocytes migrate into the retina from the optic nerve (e.g., Stone and Dreher, 1987; Huxlin et al., 1992). These results suggest that the neuroepithelium of the retina is not competent or loses its potential very early in development to generate astrocytes in the nerve fiber layer.

In theory, the optic nerve should be capable of generating both neurons and macroglia. The anlage of the optic nerve is structurally similar to that of the rest of the neural tube in that it consists of a pseudostratified neuroepithelium surrounding the optic canal. The neuroepithelium is a heavily mitotic zone until the time it disappears around E16–17 (Skoff et al., 1976a). One line of evidence suggests that the nerve is intrinsically capable of generating both neurons and macroglia, while another line of studies suggests that oligodendrocytes and most astrocytes are derived from progenitors migrating into the nerve. Cultures prepared from mouse optic stalk early in development (Theilers stage 16-19) have the potential to generate both neurons and glia but the neuronal potential is quickly lost a half-day later (Juurlink and Fedoroff, 1980). The potential to generate neurons correlates inversely with the invasion of retinal axons into the optic nerve. Once retinal axons invade the optic nerve, the neuronal capacity is lost. This intriguing observation suggests that axons may have a direct effect upon the fate and/or survival of neuroepithelial cells in certain regions of the brain. The chicken optic nerve also has the capacity to generate neurons (Giess et al., 1990) but apparently not oligodendrocytes (Giess et al., 1992). It is unclear if this inability is due to the lack of a developmental signal in the optic nerve occurring early in development or is due to migration of oligodendrocyte progenitors from the brain. In support of an extrinsic source for oligodendrocytes in the nerve, evidence for migration of a progenitor cell (O-2A), which can generate in tissue culture both oligodendrocytes and a subtype of astrocyte (type 2) from the diencephalon into the nerve around E18 has been shown (Small et al., 1987).

The evidence for the hypothesis that the ventricular zone consists of fate-restricted sites, which are destined to give rise to different types of neurons and glia, continues to mount, but its confirmation requires additional research. How early in development such fate-restricted zones might develop and the physical size of such zones is unclear. Likewise, how cells in the neuroepithelium interact with each other to alter their fate is uncertain, but recent evidence suggests that neuroepithelial cell to neuroepithelial cell contact and the phase of their cell cycle are important factors in determining the fate of neurons in the neocortex (McConnell and Kaznowski, 1991). The subventricular zone has long been considered to be the site of origin for macroglia in postnatal development (Paterson et al., 1973). The subventricular zone generates primarily astrocytes and oligodendrocytes but may also have the potential to generate neurons, at least when these cells are placed into culture (Reynolds and Weiss, 1992; Lois and

Alvarez-Buylla, 1993). These cells populate the corpus callosum, central white matter tracts in the cerebrum, and in the gray matter (Levison and Goldman, 1993; Luskin et al., 1993). The extent of their migration from the subventricular zone and their fate may be temporally related as cells leaving the zone of neonates generate both astrocytes and oligodendrocytes, whereas cells migrating from ventricular zone at 2 weeks differentiate mostly into oligodendrocytes (Levison and Goldman, 1993). The migration of cells away from the subventricular zone into the surrounding neuropil seems fairly restricted with most of the movement occurring in the lateral plane and little in the anteroposterior directions (Levison et al., 1993). However, evidence also supports the idea that glial progenitor cells are capable of migrating over considerable distances from one region of the developing cerebrum to settle into another brain region (Price and Thurlow, 1988). This hypothesis is strongly supported by transplantation and tissue culture studies that demonstrate migration of immature glia over long distances (e.g., Lachapelle et al., 1984).

The radial glial cell is generally recognized as the first subtype of glia to appear in the brain (Misson et al., 1991). This bipolar cell is present when neurons are being generated and migrating into the mantle layer. Depending on the species, radial glia may or may not be glial fibrillary acidic protein$^+$ (GFAP) (Cameron and Rakic, 1991); however, they express several unique antigens which are not expressed by neuronal precursors and can be used to distinguish them from neuronal precursors (Misson et al., 1991). This cell type is now clearly recognized as the direct source for some astrocytes found in the gray and white matter (Misson et al., 1991), confirming the hypothesis of Ramón y Cajal (1955). Ramón y Cajal's hypothesis was based upon static Golgi impregnations of glia at various early stages of development; more recent studies have used direct methods to show their transformation into astrocytes in the cerebrum and in the spinal cord (Voigt, 1989; Culican et al., 1990). Certainly, radial glia give rise to astrocytes in both the gray and white matter of brain and cord, but can they generate oligodendrocytes as well? This idea is not novel and was proposed by Penfield in the 1920s (Penfield, 1924). Recent publications continue to present circumstantial evidence that radial glia in certain regions of the brain can generate oligodendrocytes (e.g., Choi and Kim, 1984; Hirano and Goldman, 1988). The Warf study (1991), which shows migration of oligodendrocyte precursors out of the ventral half of the cord, occurs when apparently only radial glia are present; this research, along with the histological studies, supports the idea for an oligodendrocyte origin from radial glia. If further research confirms this hypothesis, then our concept of this cell subtype as being solely within the astrocyte lineage may be incorrect. The phenotype of the radial glial cell is certainly distinctive but may bear no relevance as to the type of the cells it is capable of generating. Future research may show that there are subpopulations of radial glia that are capable of generating only astrocytes, only oligodendrocytes, and, still others, both. This discussion serves to highlight the idea that, while we have made considerable progress in understanding the time of origin of radial glia in the brain, their role in neural migration and the ability of some radial glia to form astrocytes, much is still unknown about their developmental potential.

In the brain, immunocytochemical staining of embryonic rat cerebrum suggests that the ventricular zone consists of separate precursors for astrocytes and oligodendrocytes (LeVine and Goldman, 1988a, 1988b). At E16, two populations of cells can be detected in the ventricular zone, one cell population is vimentin$^+$ with the morphology of radial glia and another population is GD3$^+$, carbonic anhydrase$^+$, and iron$^+$. These latter cells are large and round with thick processes. Analysis of transitional forms suggest that the vimentin$^+$ cells turn into astrocytes, whereas the other cells contribute to the oligodendrocyte lineage. *In situ,* GD3 is expressed by cells which appear to be solely in the oligodendrocyte lineage but it is also expressed by subpopulations of neurons and it can be argued that it is not a unique cell type marker. In support of the hypothesis that the oligodendrocyte lineage is established very early in development, message for a specific myelin transcript (DM20) has been found in the rodent cerebrum around E15 (Timsit et al., 1992). These studies show that subpopulations of glial cells can be detected immunocytochemically or with *in situ* hybridization methods within the cerebral neuroepithelium in midembryonic development. While caution must be observed in drawing conclusions about cell lineages from these studies, the data clearly show some cells in the astrocyte and oligodendrocyte lineage diverge quite early in embryonic development.

With time, proliferation in the ventricular zone comes to a halt and this pseudostratified layer changes into a single-cell layer termed *ependyma.* The subventricular zone, beneath the ventricular layer, becomes the proliferative zone for macroglia in postnatal life and even in adults (e.g., Paterson et al., 1973). This layer remains quite large in certain regions of the adult brain and is thought to be a slowly proliferating zone capable of giving rise to

both astrocytes and oligodendrocytes (e.g., Smart, 1961; and see discussion above).

Lineages of Macroglia in Postnatal Development

At issue is the question of whether there are separate precursors for astrocytes and oligodendrocytes in the brain or whether a bipotential cell exists that generates both astrocytes and oligodendrocytes. The answer is extremely complex because it involves knowledge of *when* lineages diverge in the brain, clarification of the distinction between what cell lineage is *in situ* versus a cells' potential to alter its lineage when the normal external environment is changed, and it even hinges on the definition of astrocytes and oligodendrocytes (Skoff and Knapp, 1991a). Evidence from *in situ* studies and extrapolation of *in vitro* data to the animal suggests that both situations occur *in situ*. However, the extent to which data from tissue culture can be extrapolated to the *in situ* condition must be cautiously interpreted in terms of cell lineage. Information gained from tissue culture often involves experimental manipulation of cells, and it is easy to confuse cell lineage (ancestry) with the developmental potential of a cell. We use the term developmental potential or plasticity to refer to a cell's capacity to alter its *normal* developmental path (see end of this chapter). It is possible to know the lineage of a cell type without knowing whether environmental factors or what mechanisms direct the fate of a particular cell type. Of course, most lineage studies provide information not only about lineage *per se* but also other subproperties about lineage (e.g., whether it is determinate or indeterminate) (Turner et al., 1990; Jacobson, 1991).

Two approaches have been used to study glial lineages; the first we describe as an "anterograde" method and involves the tracing of glial lineages forward from ventricular cells to mature glia in young adults; the second we refer to as a "retrograde" method and involves trying to trace lineages backwards from mature cell to ventricular cell. In both approaches, similar or different methodologies may be used but retroviral labeling or injection of tracer dyes are associated with the "anterograde" approach. *In vivo,* these methods have been extremely helpful in delineating neuronal lineages beginning with the work of Sanes et al. (1986). Several studies have described clonal lineages for neurons and astrocytes or for neurons and oligodendrocytes (e.g., Galileo et al., 1990; Williams et al., 1991; Levison and Goldman, 1993) while another study indicates that neurons, astrocytes and oligodendrocytes are derived from separate progenitor cells in the cerebral cortex (Luskin et al., 1993). The results from these studies should not necessarily be viewed as contradictory for the studies were done at different times and in different locations of the brain and, most significantly, it is likely that clonal potentiality is quite diverse throughout the brain. Only recently have we begun to obtain information about macroglial lineages (Levison and Goldman, 1993; Luskin et al., 1993). Why have we learned so much about neuronal lineages using retroviral methodology and so little about glial lineages *in situ* within the last five years? A prerequisite for such studies is the ability to correctly identify all the clonal progeny of a single, labeled progenitor cell. Neuronal precursors complete their division in a relatively short span and their progeny differentiate relatively slowly into morphologically distinct subsets of neurons. When these cells are visualized with beta-galactosidase stain, they are easily identified by their distinctive shape and position in cortical layers or in spinal cord laminae. In contrast, division of glial precursors is protracted throughout development and precursors persist even in adult animals. Identification of all glia in a clone may be difficult because glial precursors or immature glia have very little cytoplasm and may not express adequate levels of astrocyte or oligodendrocyte specific markers to be detected with immunocytochemistry. Even identification of mature glia can be difficult if the conditions of tissue preparation do not adequately preserve the morphology and antigenic characteristics of the cell. In the study by Luskin and McDermott (1994) electron microscopy was utilized to visualize the beta-galactosidase reaction product within each cell and to definitively characterize all the cells within a clone. In this study, discrete clones were found for astrocytes and oligodendrocytes. In the study by Levison and Goldman, about 15% of the clones were mixed. The differences in results between the two studies could be due to number of clones analyzed (Luskin and McDermott, 1994) or in the identification of discrete clones (Levison and Goldman, 1993).

Although clonal analysis of glial lineages *in situ* is relatively limited, several studies have examined glial lineages in cultures by clonal analysis with retroviruses (Vassye and Goldman, 1990; Lubetski et al., 1992; Levison and Goldman, 1993) or by single-cell dispersion (Carnow et al., 1991). These studies show that the vast majority of clones (>97%) give rise to either astrocytic or oligodendrocytic colonies and 3% or less give rise to mixed colonies. Lubetzki et al. (1992) found mixed clones only when the medium is changed from serum-free to serum-containing media. The findings of the retroviral studies that most clones

generate either astrocytes or oligodendrocyte mimics the results of the cell dispersion study by Carnow and collaborators (1991). These mutual observations suggests that the retrovirus is randomly taken up by the different progenitor cells in these neonatal cultures, and retrovirally labeling is a legitimate tool for cell lineage analysis. These studies have important implications regarding not only for cell lineage *in situ* but also *in vitro* because they show that the vast majority of astrocytes and oligodendrocytes found in these cultures are derived from clonal cells directed to one or the other macroglial lineage. If the data from the culture studies is representative of the *in situ* condition, then this implies that a common progenitor cell is not a major source for macroglia generated in postnatal development. However, the studies also strongly suggest that a progenitor cell exists that is capable of generating both astrocytes and oligodendrocytes. The phenotype of this clonal cell is unknown from these studies, but in terms of the cell's commitment to a specific lineage, the two most likely possibilities is a cell that is uncommitted and bipotential or it may be a cell that is directed along the oligodendrocyte lineage and is shifted back toward a bipotential stage (see discussion below).

A "retrograde" approach to the study of glial lineages has been used in a number of classical studies. With the development of good fixatives and perfusion methods in the early 1970s, electron microscopy or electron microscopy combined with thymidine autoradiography was used to study the morphology of immature glia (reviewed in Wood and Bunge, 1984). Fine structural analysis of proliferating cells in postnatal development revealed that astrocytes and oligodendrocytes in the early stages of differentiation are capable of dividing (Mori and Leblond, 1969, 1970; Skoff et al., 1976a). In the postnatal optic nerve, the vast majority (>80%) of 1 hour-pulsed thymidine-labeled cells have the phenotype of astroblasts or oligodendroblasts (Figures 8-1 and 8-2) (Skoff et al., 1976a). The oligodendrocytes undergo a gradual phenotypic transition from a proliferating "light" phase" to a nonproliferating "medium" and "dark" subtype characteristic of the mature, myelinating cell (Imamoto et al., 1978). These studies were interpreted to mean that the lineage for astrocytes and oligodendrocytes have already diverged postnatally and that most macroglia are generated directly from proliferation of their own cell type. Because all the proliferating cells cannot be identified in these preparations, it does not eliminate the possibility that a common progenitor cell divides and functions as a stem cell to produce more progenitors, which, in turn, generate astroblasts and oligodendroblasts. These early studies did not utilize immunocytochemical markers to identify the cells so their classification as astrocytes and oligodendrocytes has been questioned. More recently, the expression of oligodendrocyte and astrocyte specific markers has been studied in proliferating cells during postnatal development. The majority of proliferating cells in optic nerve or in presumptive white matter tracts of the brain express markers of committed cells at the time when the majority of glia are being generated (Skoff, 1990; Skoff and Knapp, 1991b; Skoff et al., 1994). During the first postnatal week in the optic nerve when the majority of astrocytes are generated, up to 40% of the proliferating glia in the optic system are GFAP$^+$ (Skoff, 1990). During the second postnatal week, when the majority of oligodendrocytes are generated, 30 to 100% of the dividing cells in presumptive white matter tracts immunostain with an oligodendrocyte specific antibody (AOO7) and a smaller percentage (10 to 15%) with another, slightly later-appearing oligodendrocyte specific antibody (RmAB) (Skoff and Knapp, 1991b; Skoff et al., 1994). The phenotype of the GFAP$^+$ astroblasts and the glycolipid$^+$ oligodendroblasts are quite different from each another, with the immature astroblasts having coarse, tapering processes and the oligodendroblasts having very long, thin processes. Morphologically, these immunostained cells match closely in size and cytoarchitecture those seen with the electron microscopic autoradiographic studies. These results imply that the vast majority of proliferating cells are already in one or another of the macroglial lineages. In viewing lineage in terms of cell ancestry, then, the immediate precursors for most astrocytes and oligodendrocytes are cells already within their own lineage (Figure 8-3). These findings do not negate the existence of a bipotential cell in postnatal development nor do they address the issue of when the astrocyte and oligodendrocyte lineages diverge prenatally. Taken together, the *in situ* prenatal and postnatal studies as well as the retroviral studies support the hypothesis that there are separate lineages for astrocytes and oligodendrocytes in postnatal development.

Role of O-2A Cells in the Postnatal Brain

In contrast to the hypothesis that the lineages for astrocytes and oligodendrocytes have diverged in postnatal rodent development, the hypothesis that a bipotential glial progenitor is the postnatal source for oligodendrocytes and type 2 astrocytes was proposed in the past decade (Raff et al., 1983a). Oligodendrocytes are thought to "develop from dividing progenitor cells" in the first postnatal week and

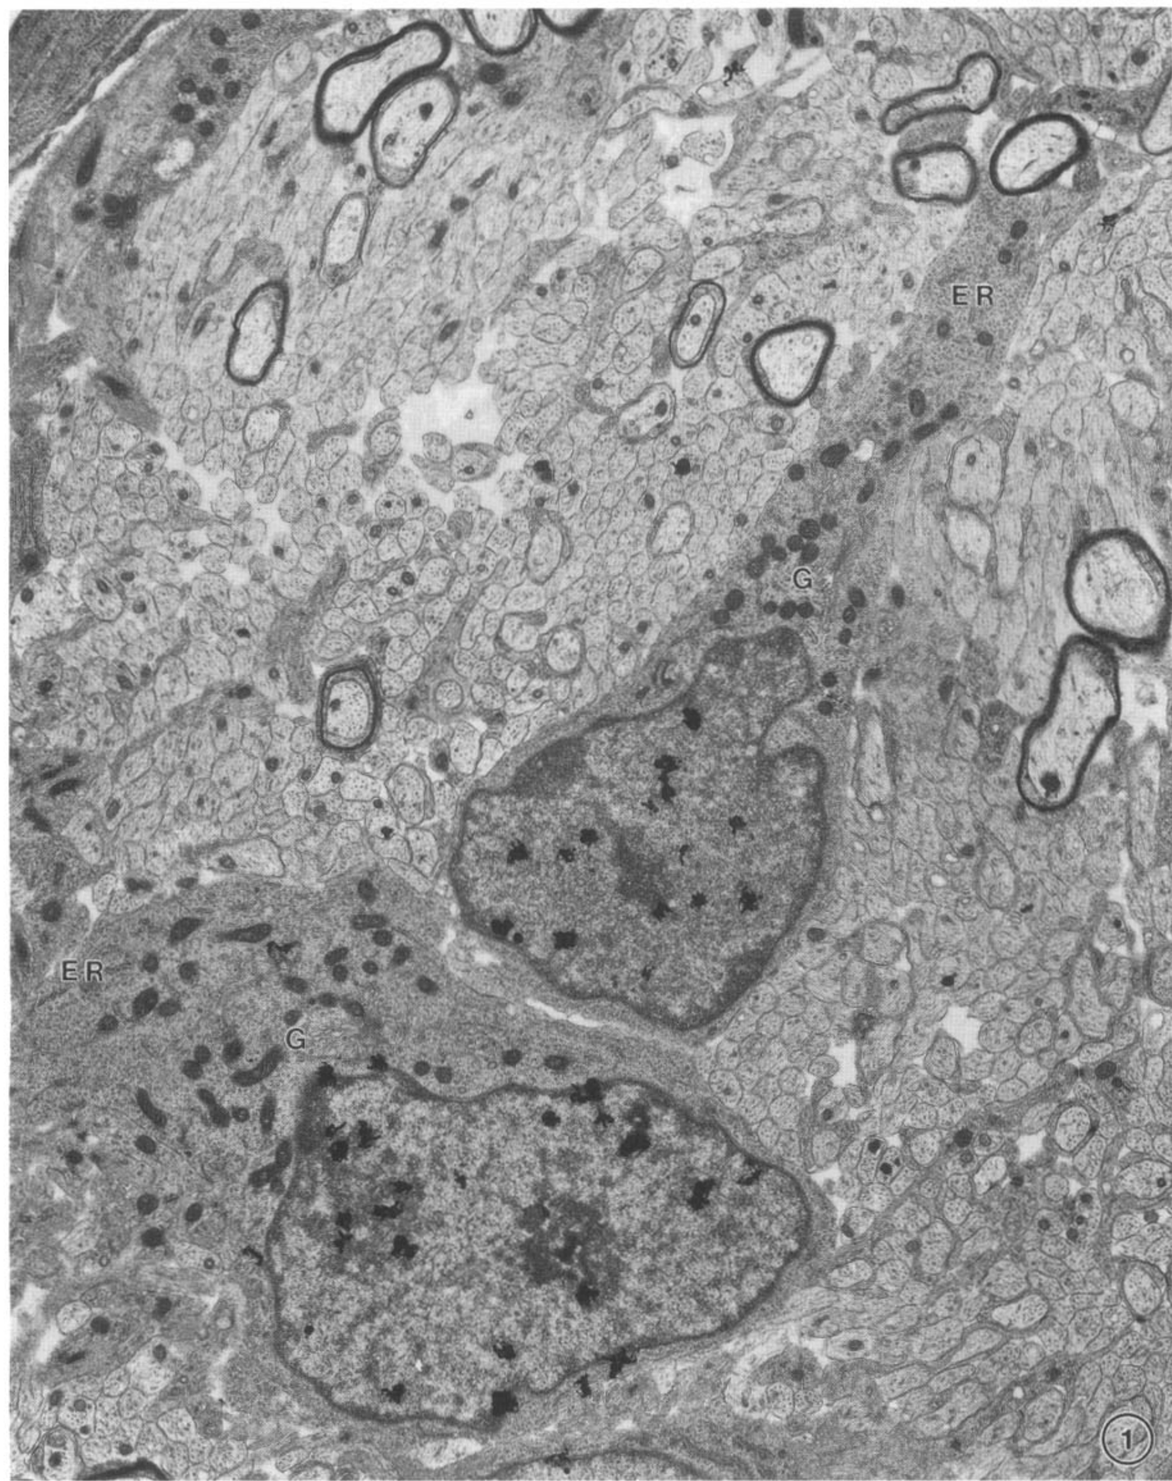

FIG. 8-1. This low-power electron microscopic autoradiogram is from the optic nerve of a 10-day-old postnatal rat. The rat was injected with tritiated thymidine 1 hour before sacrifice. Silver grains overlie the nuclei of two cells, indicating that these cells are in the S phase of the cell cycle. The cells exhibit the characteristic features of immature oligodendrocytes. Contrast them with the immature astrocyte in Figure 8-2. The cytoplasm of these oligodendroblasts is electron-dense and packed with free ribosomes, small mitochondria, Golgi apparatus (*G*), and rough endoplasmic reticulum (*ER*). The endoplasmic reticulum in these young oligodendrocytes is of narrow caliber and irregularly studded with ribosomes. The rough endoplasmic reticulum in oligodendroblasts is usually not stacked and prominent as in mature forms but scattered throughout the cytoplasm. A characteristic feature of oligodendroblasts is that the nucleus is situated at one end of the pole and the cytoplasm at the other end. The process of the oligodendroblast appears to be in contact with a myelin sheath, but it cannot be determined from this section. The cisternae of the Golgi apparatus (*G*) are narrow and closely apposed one on top of the other. Additional morphologic features distinguishing immature oligodendrocytes from astrocytes are detailed in Skoff et al. (1976a).

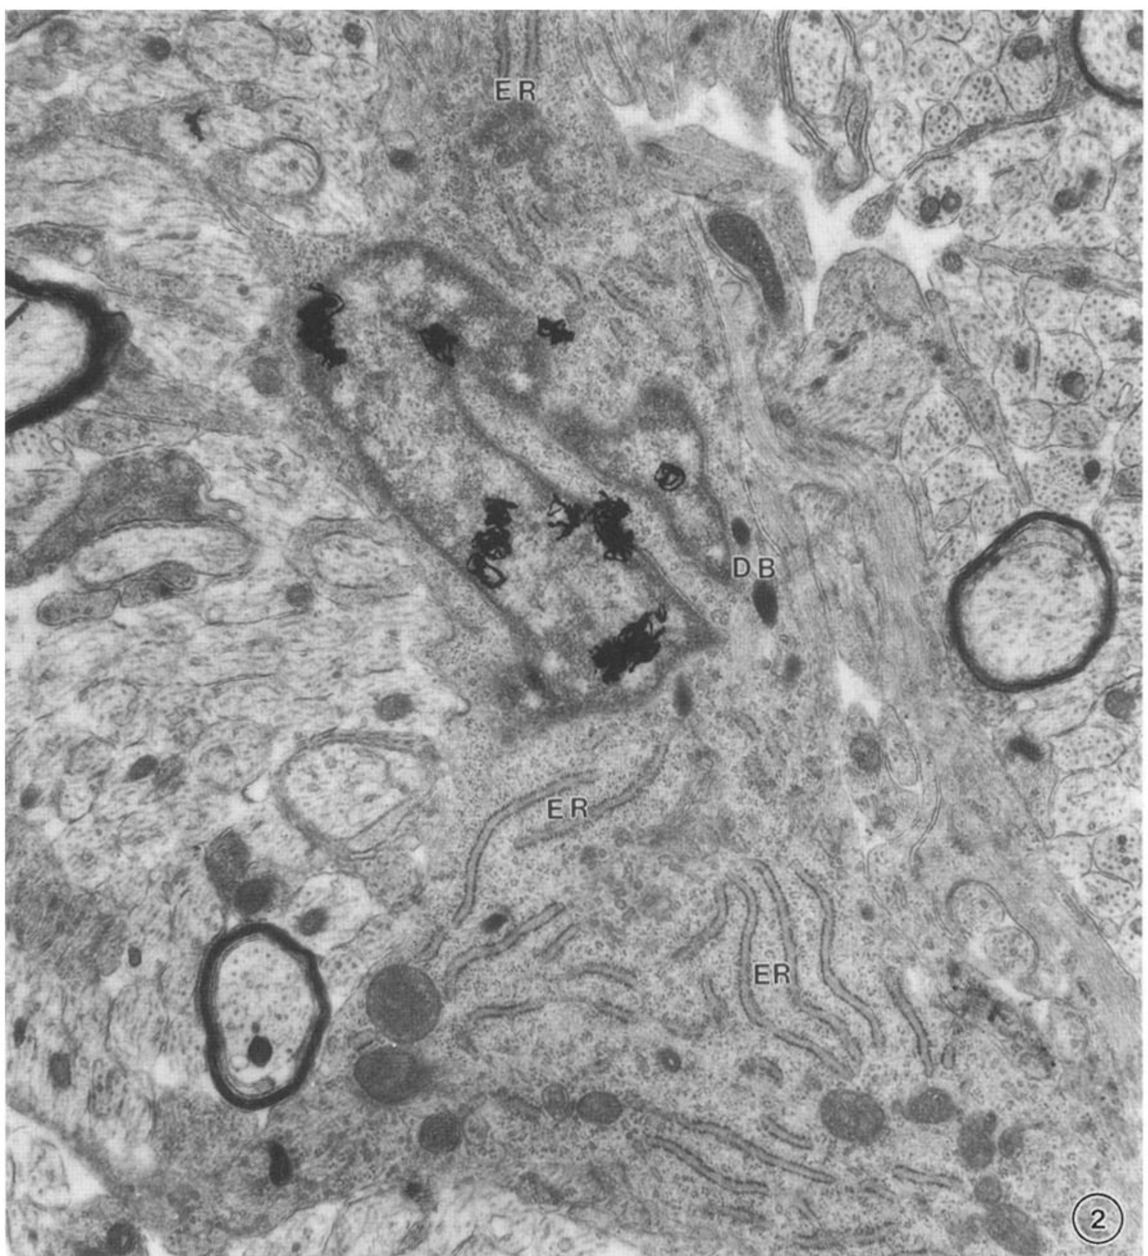

FIG. 8-2. This electron microscopic autoradiogram illustrates an immature astrocyte in the S phase of the cell cycle. Silver grains overlie the nucleus of this cell, which has been grazed near its edge. Such irregular contours are typical of astrocytes. Another view of this same cell is shown in Figure 6 of Skoff et al., 1976a. The wide-bore cisternae of the rough endoplasmic reticulum (*ER*) is filled with a floccular material and its membranes are evenly studded with ribosomes. Note how prominent the ER is in this cell compared to that in the oligodendroblasts in Figure 8-1. Numerous dense bodies (*DB*) are also frequently found in immature astrocytes but rarely in oligodendrocytes. Note also the irregular contours of the astrocytes' cytoplasm and how it radiates away from the nucleus in several directions. The paucity of mitochondria and free ribosomes in astrocytes is in sharp contrast to that of oligodendrocytes. It should be mentioned that immature astrocytes have few or lack intermediate filaments at this stage in their developnment.

type 2 astrocytes are thought "to develop from dividing progenitor cells beginning in the second week" (Raff, 1989). This bipotential O-2A cell is, like its *in vitro* counterpart, uncommitted until around the time of cell division, at which time growth factors (platelet-derived growth factor and ciliary neuronotrophic factor) drive them into becoming type 2 astrocytes or oligodendrocytes. The properties of these cells in culture is discussed below.

Since large numbers of O-2A cells are readily de-

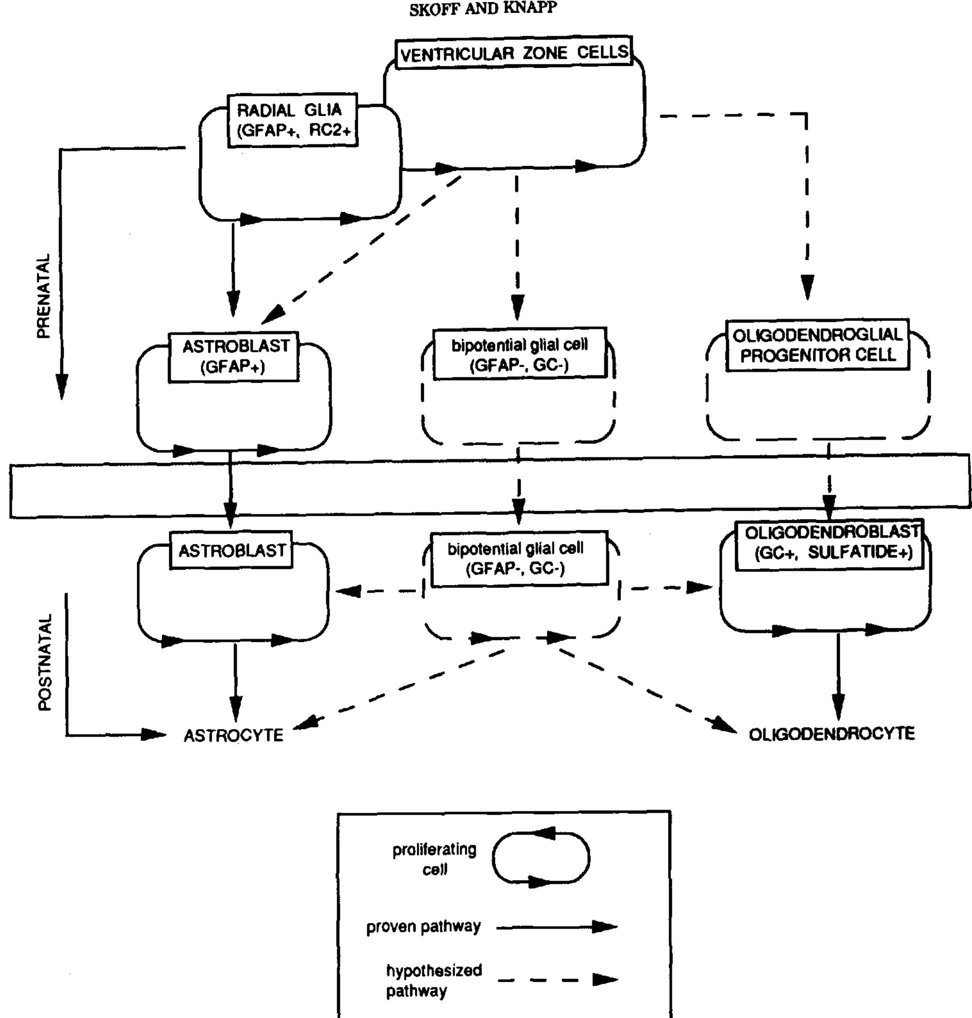

FIG. 8-3. This diagram depicts the scheme of gliogenesis in rodent brain combining information from many *in situ* studies. Solid lines indicate pathways for which evidence exists from *in situ* studies, while the dotted lines represent pathways for which there is less evidence. The pathways represent a simplified scheme of gliogenesis for all astrocytes and all oligodendrocytes. Future studies may reveal additional pathways for the subtypes of astrocytes and oligodendrocytes. [From Skoff and Knapp, (1991b), with permission.]

tected in tissue culture studies, they should also be detectable *in situ* if they play a major role in macroglial development. Studies with the A2B5 antibody *in vivo* have not reliably detected O-2A cells in tissue sections, partly perhaps because of the strong reactivity of the antibody with intracellular epitopes in neurons, which may mask surface staining on the glial cells (Eisenbarth et al., 1979; Fredman et al., 1984; Miller et al., 1989a). This staining has prevented the identification of the O-2A phenotype with this antibody in cells during development *in situ.* Since O-2A cells have a high rate of proliferation compared to GC^+ oligodendrocytes or $GFAP^+$ type 2 astrocytes in culture, it has been suggested that one contribution of O-2A cells during development might be as a source for new glial cells during expansion of the glial population. However, it should also be noted that $GFAP^+$ astrocytes and $glycolipid^+$ or MBP^+ oligodendrocytes *can* divide *in vitro.* In one study, 25% of the $GFAP^+/A2B5^+$ type 2 astrocytes grown in serum-containing medium incorporated [^{3}H]thymidine after continuous exposure for a couple of days (Raff et al., 1983a). Our results have shown that 1 to 2% of AOO7 or $R\text{-}mAB^+$ cells, and 1 to 3% of MBP^+ cells grown in serum-containing medium take up the proliferation marker bromodeoxyuridine after 1- or 18-hour pulses, respectively (Knapp, 1991; Knapp and Skoff, 1993). O-2A cells are therefore not the sole source of newly generated glia, even in cultures.

The common lineage for the progeny of the O-2A cells suggests they share a common function, and it is hypothesized that both are specialized for myelination (ffrench-Constant and Raff, 1986). The role of the oligodendrocytes in myelin formation is clearly defined, but the function of the "type 2" astrocyte is more circumstantial, owing to the problem of identifying $A2B5^+/GFAP^+$ cells *in situ,* as discussed above. Morphological studies in the optic nerve described a subpopulation of $GFAP^+$ cells with cell bodies located far from the pial surface whose fine, unbranching processes are longitudinally ori-

ented, running parallel to axons (Miller et al., 1989b). The processes of these astrocytes abut nodes of Ranvier and do not form endfeet on blood vessels or on the pial surface (ffrench-Constant and Raff, 1986). These astrocytes are suggested to be the *in vivo* correlates of the type 2 astrocyte (ffrench-Constant and Raff, 1986; Miller et al., 1989a, 1989b) described in culture since their time of origin and staining with J1 and NSP antibodies correlates with the staining and origin of type 2 astrocytes *in vitro*. This idea is appealing, since it suggests that both types of cells derived from O-2A progenitors are functionally involved with the process of axonal ensheathement and conductance of axon potential along a nerve. A study in which single glia are intracellularly filled with Lucifer Yellow, astrocytes fitting this description are not found (Butt and Ransom, 1989). Instead, all the astrocytes examined in this study have one or more processes that contact the pial surface regardless of the orientation of their processes (Butt and Ransom, 1989). Suarez and Raff (1989) and Sims and Gilmore (1991) observed that some astrocytes whose processes abut the pia also contact nodes of Ranvier. These findings contradict the idea that nodal association falls to a specific type of astrocyte whose cell body lies in the more interior portions of the nerve (ffrench-Constant and Raff, 1986; Miller et al., 1989a, 1989b).

The type 2 astrocytes in the optic nerve are described as being generated in a second wave after oligodendrocyte formation (Miller et al., 1985). Based upon quantitative immunohistochemistry at the light microscopic level, they should constitute the majority of the astrocytes in the optic nerve. However, a quantitative autoradiographic study of glial proliferation failed to find evidence for a second wave of astrocyte formation (Skoff, 1990). Cell proliferation in the rat optic nerve after 14 days postnatal drops dramatically and the few cells generated after the second postnatal week are typical oligodendrocytes when viewed ultrastructurally. If type 2 astrocytes are present in the nerve, they would have to be generated in a single wave before and overlapping with oligodendrocyte formation. Since different growth factors (platelet-derived growth factor and ciliary neuronotrophic factor) are thought to instruct O-2A cells into becoming oligodendrocytes or type 2 astrocytes *in situ,* this means that both of these growth factors need to be present at the same time in the optic nerve as oligodendrocytes and type 2 astrocytes are generated. If these growth factors are present at the same time and distributed fairly randomly throughout the nerve, it is unclear how O-2A progenitors could distinguish between them, divide, and their progeny select to enter either the oligodendrocyte or astrocyte lineage.

TISSUE CULTURE STUDIES

Although the preponderance of evidence suggests that oligodendrocytes and astrocytes *in situ* derive from lineages that are separate during postnatal development, the picture that has emerged from tissue culture studies is strikingly different. A study in the early 1980s suggested that there is a progenitor cell in dispersed cultures derived from postnatal central nervous system tissues that can develop into an oligodendrocyte or into a type of astrocyte, depending on the culture conditions (Raff et al., 1983a). When these bipotential, O-2A progenitor cells are cultured in serum-free medium they develop largely into oligodendrocytes, suggesting that this is the constitutive pathway. However, factors in serum apparently deter O-2A cells from their normal developmental pathway, causing them instead to develop largely into process-bearing, $GFAP^+$ astrocytes, which have been termed "type 2" astrocytes (Raff et al., 1983a). According to the O-2A theory, the flat, "type 1" astrocytes belong to a separate lineage and have not been observed to transform into process-bearing type 2 astrocytes under culture conditions so far examined (Raff et al., 1983b). Thus, in terms of lineage relationships, the O-2A theory suggests that type 2 astrocytes are more closely related to oligodendrocytes than they are to type 1 astrocytes. Although the original O-2A studies were done exclusively on cultures derived from optic nerve, similar observations have been made in cultures derived from cerebellum (Levi et al., 1986; Trotter and Schachner, 1989) and cortex (Trotter and Schachner, 1989).

Properties of O-2A Cells

The O-2A cell was initially identified by its reactivity with the A2B5 monoclonal antibody (Eisenbarth et al., 1979; Raff et al., 1983a). In typical experiments, when cells are grown in serum-containing medium, most cells that immunostain for A2B5 are also $GFAP^+$ process-bearing astrocytes but when grown in the absence of serum, most A2B5 cells are GC^+ (Raff et al., 1983a). It was concluded that a bipotential cell with A2B5 reactivity gives rise to the majority of type 2 astrocytes and oligodendrocytes within the cultures. In other studies, cells are initially exposed to A2B5 and then cultured for several days. Over 90% of the GC^+ oligodendrocytes that subsequently developed under serum-free conditions have residual A2B5 staining on their surface, suggesting

that a population of A2B5$^+$ cells are the direct precursors of oligodendrocytes in the cultures (Raff et al., 1983a). Further studies to characterize these O-2A cells with regards to their antigenicity and phenotype show that the cells have a simple, bi- or tripolar morphology (Temple and Raff, 1986; Small et al., 1987), immunostain for vimentin (Raff et al., 1984), are highly motile (Small et al., 1987) and proliferate with cell cycle times of approximately 18 to 20 hours (Noble et al., 1988). They share some electrophysiological properties with neurons, including a neuronal form of voltage-dependent sodium channel, and non-NMDA glutamate-activated ion channels (Barres et al., 1990). The ion channel phenotypes of O-2A cells and their differentiated progeny are distinct from one another (Barres et al., 1990), and there are indications that channel phenotype can differ among glia derived from different parts of the central nervous system (Sontheimer et al., 1989). Soluble factor(s) secreted by type 1 astrocytes in the cultures increase motility and proliferation of O-2A cells (Noble and Murray, 1984), and these effects can be mimicked by platelet-derived growth factor (Noble et al., 1988), suggesting physiological control mechanisms for expansion of the progenitor population *in vivo*. Other factors shown to be mitogens for O-2A cells include glial maturation factor (Hunter and Bottenstein, 1990), factors secreted by neuronal cell lines (Hunter and Bottenstein, 1990), and both α- and β-fibroblast growth factors (Besnard et al., 1989; Bogler et al., 1990; McKinnon et al., 1990). Although platelet-derived growth factor induces O-2A proliferation, the effect is only short term, and in the continued presence of platelet-derived growth factor, O-2A cells eventually drop out of the cycle and differentiate into oligodendrocytes (Noble et al., 1988). Fibroblast growth factor blocks progenitor cell differentiation and promotes continued proliferation, while at the same time upregulating the synthesis of platelet-derived growth factor receptors. Exposure to platelet-derived growth factor then induces migration (Small et al., 1987; Bogler et al., 1990) and differentiation (McKinnon et al., 1990). In this way, platelet-derived growth factor and fibroblast growth factor might act together to coordinate the timely differentiation of O-2A cells. Precursors of O-2A cells that are A2B5$^-$ also apparently respond to platelet-derived growth factor with increased proliferation and enhanced generation of O-2A cells (Grinspan et al., 1990).

In the optic nerve studies, flat astrocytes are reported to be mostly A2B5$^-$ while process-bearing cells are A2B5$^+$. This suggests a possible lineage relationship among the process-bearing cells, which includes both oligodendrocytes and astrocytes with processes and their precursor, the small, undifferentiated cells. In several more recent studies, the A2B5 antibody has been shown to immunostain a sizeable subpopulation of cortical and cerebellar flat, bed-layer astrocytes (Drago et al., 1990; Knapp, 1991; Vaysse and Goldman, 1992), although such immunostaining was never observed in the optic nerve studies that defined the O-2A cell (Raff et al., 1983a, 1983b). A2B5 is now well known to react with a variety of antigens, including multiple gangliosides and sulfatide (Kundu et al., 1983; Fredman et al., 1984; Majocha et al., 1989). Thus, cell types that are not closely related to each other either phenotypically or by lineage can immunostain for A2B5 by virtue of its affinity for different antigens. Such is the case for certain neurons that are A2B5$^+$ (Eisenbarth, 1979; Fredman et al., 1984), which are not in the same lineage as glial cells. The expression of A2B5 also appears to be inducible by growth factors within culture medium (Drago et al., 1990). It is now clear that A2B5 is not a monospecific antibody but that it reacts with a variety of epitopes and cell types, and its reactivity can be modulated by culture conditions.

Switching Glial Lineages In Vitro

A major finding of the O-2A studies is that oligodendrocytes and astrocytes retain their bipotentiality even after beginning to express what are considered to be cell-type specific markers (Raff et al., 1983a; Raff et al., 1984; Temple and Raff, 1986). In examining large populations of cells, GC$^+$ oligodendrocytes initially grown in serum-free medium can be placed in serum-containing medium and will either become GC$^-$/GFAP$^+$ or express a mixed GC$^+$/GFAP$^+$ phenotype. Likewise, the reversal of GFAP$^+$, type 2 astrocytes into GC$^+$/GFAP$^-$ or GC$^+$/GFAP$^+$ cells can be accomplished by switching culture conditions from serum-containing to serum-free media. After initial expression of GC or GFAP, developmental pathways can be switched for either 24 hours (Raff et al., 1983a) or 48 hrs (Raff et al., 1984; Temple and Raff, 1986) and the switch does not require cell division (Temple and Raff, 1986). None of these studies followed the switching of a single cell from an astrocyte to an oligodendrocyte phenotype and vice versa but the cells of mixed phenotype are thought to provide ample evidence that cells can switch from one phenotype to the other.

The original identification of cells with mixed astrocyte and oligodendrocyte phenotype are made using an antibody produced by Dr. B. Ranscht (Ranscht et al., 1982), now termed R-mAb. R-mAb

was thought to be specific for GC, but has since been shown to react with additional high specificity to sulfatide, and with lesser affinity to seminolipid and psychosine (Bansal et al., 1989). Other studies identified $GFAP^+$ cells that react with antibodies O1 and O4 (Raff et al., 1983a; Trotter and Schachner, 1989), which have been described as being oligodendrocyte-specific. We have also observed up to 10% of cells in serum-containing cortical cultures that are $GFAP^+$ and have the morphology of astrocytes, but which stain for O4 or O1 as well as for GFAP (R. P. Skoff and P. E. Knapp, unpublished observations). The O4 and O1 antibodies react primarily with sulfatide and GC, respectively, but with lesser affinity to other lipids including psychosine, seminolipid, and mono- and digalactosyldiglyceride (Bansal et al., 1989). Additionally, O4 reacts with an unidentified antigen (POA), which appears very early in glial development, even before the synthesis of sulfatide is detected (Bansal et al., 1992). In light of these multiple specificities, the results suggesting that astrocytes and oligodendrocytes can switch lineage must be cautiously interpreted. An alternative interpretation of $R\text{-}mAb^+/GFAP^+$ or $O1^+/GFAP^+$ cells is that subpopulations of astrocytes grown *in vitro* normally express antigens that react with R-mAb and O1. These astrocytic antigens might be the same or might be completely different from the antigen(s) found on the surfaces of oligodendrocytes. Interestingly, when Raff et al. (1983a) examined freshly dissociated suspensions of optic nerve or corpus callosum, $GFAP^+/R\text{-}mAb^+$ cells are not found. This suggests that a mixed phenotype ($GFAP^+/R\text{-}mAb^+$, 01^+) is not a step in the normal *in vivo* differentiation of oligodendrocytes or astrocyte. Glia with a mixed antigenic phenotype ($GFAP^+/GC^+$) have been infrequently reported in brain tissues either during normal development (Choi and Kim, 1984) or after demyelination induced by antibodies to GC (Carroll et al., 1987). If GC is expressed by astrocytes in demyelinated tissues (Carroll et al., 1987), such expression may be unrelated to normal glial lineage and may instead represent a transient expression of an inducible antigen.

A UNIFYING THEORY OF GLIOGENESIS

The cell lineage studies presented above may appear contradictory but, when taken as a whole, the *in vivo* and *in vitro* findings can be interpreted as converging into a unifying theory of gliogenesis. The *in vivo* studies point to *separate* and *early divergence* of the astrocyte and oligodendrocyte lineages. The *in vitro* studies point to a *bipotential cell* in postnatal development, which generates both oligodendrocytes and a process-bearing type of astrocyte. How can these two lines of evidence be integrated? The evidence is very strong that some glial precursor is present in postnatal development which has the potential *in vitro* to generate both types of macroglia. However, this potential is apparently not expressed *in vivo* under *normal* developmental conditions. When O-2A cells are purified *in vitro,* loaded with the long-term dye fast blue, and then transplanted into neonatal rat brain, the fast blue-labeled cells develop exclusively into oligodendrocytes (Espinosa de los Monteros et al., 1993). In a similar vein, transplantation of O-2A progenitors into demyelinated brain leads to the formation of mature oligodendrocytes (Groves et al., 1993). The data can be interpreted two ways: the microenvironment of the developing brain restricts the bipotentiality of cells phenotyped as O-2A cells in culture or the O-2A cells are all cells "committed" to the oligodendrocyte lineage. Whichever is the case, the O-2A cells are probably somewhat less differentiated than the $glycolipid^+$ (RmAb, A007), multiple process-bearing cells that have been described in postnatal brain and referred to as oligodendroblasts (Skoff and Knapp, 1991b). Alternatively, they could be $glycolipid^+$ and at the same stage of differentiation as the oligodendroblasts described in the brain but lose these surface antigens and their fine processes when dissociated and placed in culture. Regardless of the exact degree of differentiation between the O-2A cell and the oligodendroblast, the fact that a progenitor cell in culture can develop into a subtype of astrocyte, as well as an oligodendrocyte, demonstrates that extrinsic factors can modulate this cell's potential to alter its fate. Conversely, the transplantation studies demonstrate that *in situ* conditions restrict the potential of cells phenotypically defined as O-2A cells *in vitro.* A major, unresolved question is whether all or only a certain percentage of cells phenotypically identified as O-2A cells in culture have the potential to switch lineages. The bipotential property of the O-2A cells has been examined in bulk populations of cells and in nondividing cells over a short time interval (Temple and Raff, 1986). Most convincingly, the bipotentiality of immature glial cells needs to be demonstrated by following single cells over extended periods of time to show that they divide and that both astrocytes and oligodendrocytes can be generated from one cell.

If the normal fate of O-2A cells within the brain is to generate oligodendrocytes, this implies, by default, that a separate lineage or lineages exist(s) for the various subtypes of astrocytes found throughout the nervous system. Evidence that such distinct as-

troglial lineage(s) exist is shown by the transformation of radial glia into astrocytes and the large number of proliferating, GFAP+ astrocytes found in postnatal brain at times when astrocytes are normally generated.

As has been described by Jacobson (1991), lineage in many invertebrate systems is determinant, meaning that cell fate is fixed regardless of the surrounding environment. In vertebrate systems, however, lineage is usually indeterminant, meaning that cell fate is dependent on extrinsic conditions and *probabilistic.* The controversy about macroglia lineages is an excellent case in point. Integrating the current *in vivo* and *in vitro* evidence, the *in vivo* counterparts of the *in vitro* O-2A cells will generate all oligodendrocytes (and not a subset of astrocytes) in the brain with very high probability. Because this probability is very high, proliferation and differentiation of O-2A cells into oligodendrocytes in the brain can be considered their *normal* path of development. Returning, then, to the definition of cell lineage in terms of a particular cell's ancestry, the ancestors of oligodendrocytes in the postnatal brain are in a lineage separate from astrocytes. However, the *indeterminancy* of the oligodendrocyte lineage can be demonstrated when cells in this lineage are removed from the brain. They are subject to a different set of extrinsic conditions than occur within the brain and their behavior *in vitro* deviates from their normal developmental course. They now display a *plasticity* that is very infrequently observed *in situ* in normal development, and this is reflected in the cell's ability to switch its normal fate and phenotype. The critical issue is not to equate a particular cell's lineage *in situ* with this cell's plasticity *in vitro.*

9 *In vitro* studies of the development, maintenance and regeneration of the oligodendrocyte-type-2 astrocyte (O-2A) lineage in the adult central nervous system

GUUS WOLSWIJK AND MARK NOBLE

The physiological requirements for the generation of oligodendrocytes in the developing and mature central nervous system differ fundamentally. The millions of oligodendrocytes that are formed during development, together with many other differentiated cell types, participate in the formation of the complex mature central nervous system. In contrast, the generation of oligodendrocytes in the adult central nervous system has the primary purpose of maintaining homeostasis, that is, to compensate for naturally occurring oligodendrocyte cell death and to respond to demyelinating damage. Thus, in the adult central nervous system there is normally only a modest production of oligodendrocytes and large numbers of new oligodendrocytes are only generated following demyelination. This suggests that the division and differentiation of the precursor cells that give rise to oligodendrocytes in the developing and mature central nervous system may be controlled by different mechanisms. However, are these differences a reflection of differences in the *in vivo* environment of the oligodendrocyte precursor cells or are they a reflection of differences that are intrinsic to the precursor cells themselves?

Oligodendrocytes in the developing and mature central nervous system appear to be generated by two distinct precursor populations. This suggestion has come from *in vitro* studies of the oligodendrocyte-type-2 astrocyte (O-2A) lineage of the rat optic nerve, where *perinatal* and *adult* precursor cells are referred to as O-2A^{perinatal} and O-2A^{adult} progenitor cells, respectively (Wolswijk and Noble, 1989). Detailed comparisons of the properties of perinatal and adult optic nerve-derived O-2A progenitor cells have indicated that these two populations differ fundamentally in tissue culture (Wolswijk and Noble, 1989; Wren and Noble, 1989; Van der Maazen et al., 1991a; Wren et al., 1992; Borges et al., 1995) (see Table 9-1). At least some of the differences between O-2A^{perinatal} and O-2A^{adult} progenitor cells appear to be related to the differences in the physiological requirements of the developing and adult central nervous systems, respectively (Wolswijk and Noble, 1989).

Studies on O-2A^{perinatal} and O-2A^{adult} progenitor cells have also yielded new insights into (1) mechanisms that may be involved in halting the exponential increases in the number of oligodendrocytes seen during development, (2) the developmental origin of the stem cell-like O-2A^{adult} progenitor cells, (3) mechanisms that may underlie regenerative events in the oligodendrocyte lineage, and (4) factors that may hamper repair of demyelinated lesions.

COMPARATIVE PROPERTIES OF O-2A^{adult} AND O-2A^{perinatal} PROGENITOR CELLS GROWN *IN VITRO*

In this chapter, the properties of optic nerve-derived O-2A^{perinatal} and O-2A^{adult} progenitor cells are discussed. Although the O-2A lineage is also found in regions of the developing and adult central nervous system other than optic nerve (e.g., Levi et al., 1986; Behar et al., 1988; Trotter and Schachner, 1988; Gard and Pfeiffer, 1989; Armstrong et al., 1990; Vaysse and Goldman, 1990; Van der Maazen et al., 1991b; Warf et al., 1991; Barnett et al., 1993; Levine et al., 1993; G. Wolswijk, unpublished observations), O-2A progenitor cells derived from such regions have not been analyzed in as great detail as those isolated from perinatal and adult optic nerves. However, there are indications that O-2A progenitor

cells isolated from these regions may differ in some aspects from their optic nerve counterparts (e.g., Vaysse and Goldman, 1990; Van der Maazen et al., 1991b; Lubetzki et al., 1992; G. Wolswijk, unpublished observations).

O-2A progenitor cells isolated from the optic nerves of perinatal and adult rats can be induced to differentiate along two different developmental pathways. Growth of O-2A^{perinatal} and O-2A^{adult} progenitor cells in a chemically defined medium (DMEM-BS) is associated with their precocious differentiation into oligodendrocytes (Raff et al., 1983b; Temple and Raff, 1985; ffrench-Constant and Raff, 1986; Wolswijk and Noble, 1989; Chan et al., 1990), the cells that form an insulating sheath of myelin around axons in the central nervous system (Peters et al., 1976). O-2A^{perinatal} and O-2A^{adult} progenitor cells can also differentiate into type-2 astrocytes *in vitro,* but this requires the presence of an induction factor(s), such as a factor(s) found in fetal sera (Raff et al., 1983b; ffrench-Constant and Raff, 1986; Wolswijk and Noble, 1989; Lillien and Raff, 1990). It should be noted, however, that the *in vivo* existence of type-2 astrocytes is a matter of great controversy (e.g., Fulton et al., 1991; Noble, 1991; Skoff and Knapp, 1991; Chapter 8, this volume) and that the studies discussed in this review have focused primarily on the differentiation of O-2A^{perinatal} and O-2A^{adult} progenitor cells into oligodendrocytes.

When O-2A^{perinatal} and O-2A^{adult} progenitor cells are grown on monolayers of cortical astrocytes or in the presence of DMEM-BS conditioned by cortical astrocytes (Astro-CM) these cells retain their progenitor phenotype, that is, these cells are stimulated to divide and at the same time are prevented from differentiating prematurely into oligodendrocytes (Noble and Murray, 1984; Raff et al., 1985; ffrench-Constant and Raff, 1986; Wolswijk and Noble, 1989; Chan et al., 1990). Cortical astrocytes appear to be very similar to the type-1 astrocytes of the optic nerve (Raff et al., 1983a), suggesting that type-1 astrocyte-derived factor(s) may also be important in controlling the proliferation and differentiation of O-2A^{perinatal} and O-2A^{adult} progenitor cells *in vivo.* This notion is supported by observations that type-1 and cortical astrocyte-derived factor(s) are capable of supporting the division and correctly timed differentiation of embryonic O-2A^{perinatal} progenitor cells into oligodendrocytes *in vitro* (Raff et al., 1985, 1988).

In vitro studies have shown that O-2A^{adult} progenitor cells differ in many ways from their perinatal counterparts (see Table 9-1):

1. Freshly isolated O-2A^{perinatal} progenitor cells contain the intermediate filament protein vimentin (Raff et al., 1984; Wolswijk and Noble, 1989; Wolswijk et al., 1990), whereas virtually all O-2A^{adult} progenitor cells grown for 1 day *in vitro* lack intermediate filaments of any class (Wolswijk and Noble, 1989).
2. O-2A^{adult} progenitor cells have much longer cell cycle times than O-2A^{perinatal} progenitor cells when induced to divide by cortical astrocyte-derived factor(s), resulting in much slower increases in the number of O-2A lineage cells in cultures of adult optic nerve as compared to perinatal optic nerve cultures (Wolswijk and Noble, 1989).
3. When O-2A^{adult} and O-2A^{perinatal} progenitor cells are grown on cortical astrocytes or in Astro-CM, O-2A^{adult} progenitor cells express a pseudo-unipolar morphology with one major process plus several

TABLE 9-1. *Distinguishing Properties of O-2A^{perinatal} and O-2A^{adult} Progenitor Cells Grown* in vitro

Properties	O-2A^{perinatal} Progenitor Cell	O-2A^{adult} Progenitor Cell
Antigenic phenotype	O4$^-$Vimentin$^+$	O4$^+$Vimentin$^-$
Morphology	Bipolar	Unipolar
Cell cycle time	18 ± 4 h	65 ± 18 h
Rate of migration (on PLL)	21 ± 2 μm/h	4 ± 1 μm/h
Time-course of differentiation (50% differentiated)	<< 2 days	3–5 days
Developmental potential[a]	Tripotential	Bipotential
Mode of division and differentiation[a]	Symmetric	Asymmetric
Self-renewal capability[a]	Limited	Unlimited (?)
Sensitivity to complement in the absence of antibodies[b]	Insensitive	Sensitive
Sensitivity to irradiation[c]	Relatively sensitive	Relatively insensitive

PLL, poly-L-lysine.

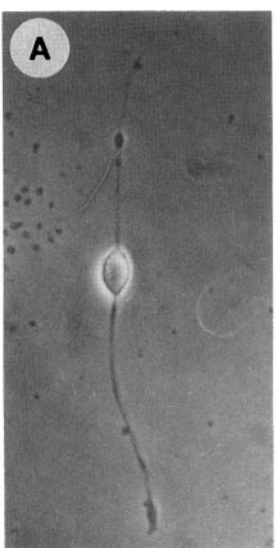
smaller and thinner processes (Wolswijk and Noble, 1989; Chan et al., 1990), while O-2A^{perinatal} progenitor cells have a characteristic bipolar morphology (Temple and Raff, 1986; Small et al., 1987) (see Figure 9-1).

4. O-2A^{adult} progenitor cells stimulated to divide by cortical astrocytes *in vitro* bind the O4 monoclonal antibody (Wolswijk and Noble, 1989), whereas proliferating O-2A^{perinatal} progenitor cells are O4$^-$ (I. Sommer and M. Noble, unpublished observations; Wolswijk and Noble, 1989; Wolswijk et al., 1990; Gard and Pfeiffer, 1990).

5. O-2A^{adult} progenitor cells migrate on average five times more slowly than their perinatal counterparts when cultured on a poly-L-lysine coated substrate in Astro-CM (Wolswijk and Noble, 1989).

6. The differentiation of O-2A^{adult} progenitor cells into oligodendrocytes or type 2 astrocytes *in vitro* takes about three times longer than is the case for O-2A^{perinatal} progenitor cells (Wolswijk and Noble, 1989).

Accumulating evidence indicates that O-2A^{perinatal} and O-2A^{adult} progenitor cells induced to divide by cortical astrocytes express their distinguishing properties in response to a single cortical astrocyte-derived factor, that is, platelet-derived growth factor (PDGF). Cortical astrocytes secrete PDGF *in vitro* and O-2A^{perinatal} and O-2A^{adult} progenitor cells grown in purified or recombinant PDGF express the same properties as those grown in the presence of cortical astrocyte-derived factor(s) (Noble et al., 1988; Raff et al., 1988; Richardson et al., 1988; Wolswijk et al., 1991b). In addition, antibodies to PDGF neutralize virtually all of the mitogenic effect in Astro-CM for O-2A^{perinatal} and O-2A^{adult} progenitor cells (Noble et al., 1988; Raff et al., 1988; Richardson et al., 1988; Wolswijk et al., 1991b). These results suggest that the intracellular responses generated following the binding of PDGF to its receptor differs in O-2A^{perinatal} and O-2A^{adult} progenitor cells, resulting in the expression of different patterns of cellular behavior. PDGF may also be important in controlling the behavior of O-2A^{perinatal} and O-2A^{adult} progenitor cells *in vivo*, as both PDGF and its mRNA are expressed in the developing and adult optic nerve (Richardson et al., 1988; Pringle et al., 1989).



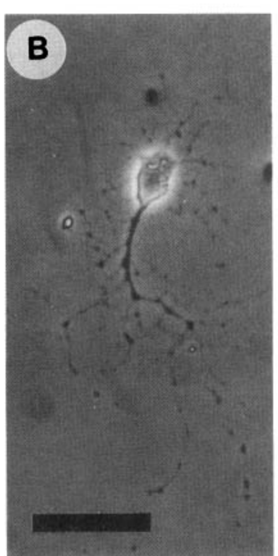


FIG. 9-1. O-2A^{perinatal} and O-2A^{adult} progenitor cells differ in their morphology when exposed to cortical astrocyte-derived factor(s) or platelet-derived growth factor. O-2A progenitor cells isolated from the optic nerves of newborn rats (A) and adult animals (B). Adult animals were grown for 3 days in Astro-CM and photographed, when still alive, through an inverted microscope. This figure illustrates that most O-2A^{perinatal} progenitor cells express a bipolar morphology *in vitro* (Temple and Raff, 1986; Small et al., 1987), while O-2A^{adult} progenitor cells predominantly have a pseudounipolar morphology (Wolswijk and Noble, 1989; Chan et al., 1990). Bar in Figure B = 50 μm.

APPEARANCE OF O-2A^{adult} PROGENITOR CELLS DURING DEVELOPMENT OF THE OPTIC NERVE AND THEIR ORIGIN

Developmental studies have suggested that the properties of O-2A progenitor cells do not gradually change with age, but that O-2A^{adult} progenitor cells appear in the developing optic nerve as a distinct population of cells and that these cells coexist with O-2A^{perinatal} progenitor cells until this latter population has disappeared from the nerve (Wolswijk et al., 1990) (see Figure 9-2). Cells that express properties of O-2A^{adult} progenitor cells in vitro can be isolated from developing optic nerves as early as postnatal day 7 (P7) (Wolswijk et al., 1990). Between the ages of P7 and P30, both O-2A^{adult} and O-2A^{perinatal} progenitor cells can be isolated, but the ratio of these two O-2A progenitor types gradually shifts in favor of O-2A^{adult} progenitor cells (Wolswijk et al., 1990). Cultures prepared from the optic nerves of adult rats only contain O-2A^{adult} progenitor cells (Wolswijk and Noble, 1989). These developmental studies have also shown that O-2A^{adult} and O-2A^{perinatal} progenitor cells express their distinguishing properties in the same culture (Wolswijk et al., 1990), thus providing direct evidence that O-2A^{adult} and O-2A^{perinatal} progenitor cells differ intrinsically from each other.

O-2A^{adult} progenitor cells appear to be derived directly from a subpopulation of O-2A^{perinatal} progenitor cells, as indicated by three separate findings. First, time-lapse cinemicroscopy studies have revealed that a subpopulation of cells with the char-

acteristics of O-2A^{perinatal} progenitor cells (i.e., cells with a bipolar morphology, short cell cycle time and high rate of migration) in cultures of P21 optic nerve grown in Astro-CM has the ability to generate unipolar, slowly dividing and migrating O-2A^{adult} progenitorlike cells (Wren et al., 1992). Second, serial passaging of populations of optic nerve cells derived from newborn rat pups [which lack O-2A^{adult} progenitorlike cells (Wolswijk et al., 1990)] onto fresh monolayers of cortical astrocytes is associated with the appearance of cells with the antigenic phenotype, morphology, and rate of division characteristic of O-2A^{adult} progenitor cells (Wren et al., 1992). After several passages, these cells become the dominant population of O-2A progenitor cells in the cultures. The O-2A^{adult} progenitor cells that appear in the cultures are generated by cells that are contained in the O-2A progenitor population at the start of the experiments, as no new O-2A lineage cells appear in the cultures when O-2A lineage cells are eliminated specifically from the cultures. Third, colony studies have suggested that some colonies of O-2A^{perinatal} progenitor cells have the ability to generate cells with some of the properties of O-2A^{adult} progenitor cells (Dubois-Dalcq, 1987; G. Wolswijk, unpublished observations). These findings are consistent with the possibility that O-2A^{adult} progenitor cells arise in the optic nerve itself and that these cells do not enter the developing optic nerve as a second population of O-2A progenitor cells.

THE MAINTENANCE OF THE O-2A^{adult} PROGENITOR POPULATION THROUGHOUT LIFE

The generation of O-2A^{adult} progenitor cells by O-2A^{perinatal} progenitor cells appears not to play a role in the maintenance of the O-2A^{adult} progenitor population in the optic nerves of adult animals, as indicated by the observation that the O-2A^{perinatal} progenitor population eventually disappears from the developing optic nerve (Wolswijk and Noble, 1989) (see Figure 9-2). Current evidence suggests that O-2A^{adult} progenitor cells express properties of stem cells, thereby allowing these cells to support their own replenishment as well as that of the oligodendrocyte population throughout life (for reviews on stem cells, see Hall and Watt, 1989; Potten and Loeffler, 1990). One stem cell-like property of O-2A^{adult} progenitor cells is the expression of long cell cycle times (Wolswijk and Noble, 1989; Wolswijk et al., 1991b; Wren et al., 1992). A further stem cell-like property of O-2A^{adult} progenitor cells is their apparent ability to undergo asymmetric division and dif-

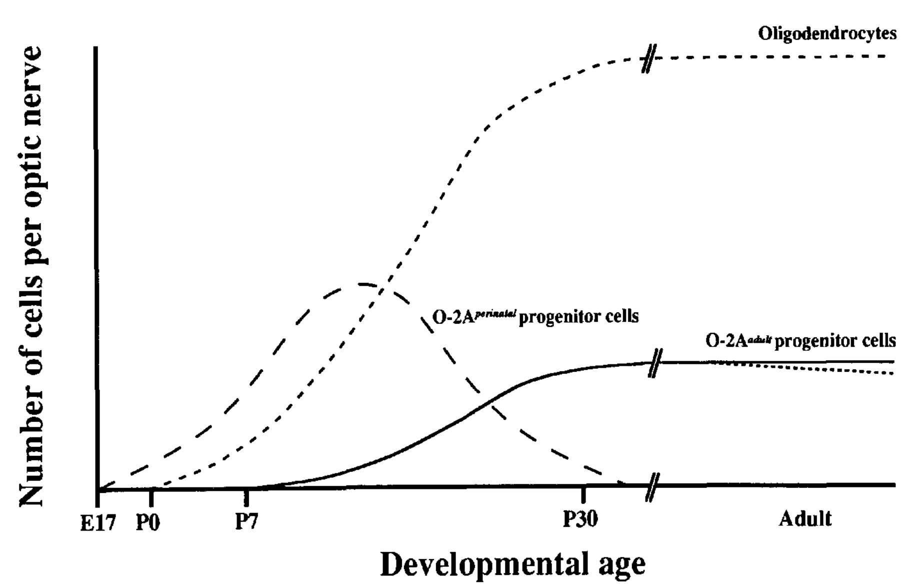

FIG. 9-2. Developmental transition in O-2A progenitor type during development of the rat optic nerve. Indirect evidence suggests that O-2A^{perinatal} progenitor cells migrate into the developing nerve at approximately embryonic day 17 (*E17*) (Small et al., 1987), while their differentiated progeny, oligodendrocytes, are first seen at around the day of birth (P0) (Miller et al., 1985). O-2A^{adult} progenitor cells appear in the nerve approximately 7 days after birth and this population of cells coexists with O-2A^{perinatal} progenitor cells until the *perinatal* progenitor population has disappeared from the nerve (Wolswijk and Noble, 1989; Wolswijk et al., 1990). The O-2A^{adult} progenitor population persists into adulthood, though there are suggestions that their number may gradually decline with age (Wolswijk and Noble, 1989; 1992; G. Wolswijk, unpublished observations). The relative cell numbers that are given are not indicative of the actual numbers of O-2A^{perinatal} progenitor cells, O-2A^{adult} progenitor cells and oligodendrocytes in the developing and adult optic nerve, but are meant to reflect the relative fluctuations in these populations as indicated by current data.

ferentiation. Indirect evidence for this has come from studies in which the composition of colonies generated by single O-2A^{adult} progenitor cells was analysed. These studies showed that oligodendrocytes tend to coexist in the same colony as dividing O-2A^{adult} progenitor cells (Wren et al., 1992). Asymmetric division and differentiation of O-2A^{adult} progenitor cells grown *in vitro* has also been demonstrated directly using time-lapse cinemicroscopy, as illustrated in Figure 9-3. This figure shows that 14 clonally-related O-2A^{adult} progenitor cells had different fates: some O-2A^{adult} progenitor cells in this particular family differentiated into oligodendrocytes, while others continued to divide at least four more times as O-2A^{adult} progenitor cells. Oligodendrocytes were generated also in branches of the family that contained dividing O-2A^{adult} progenitor cells and this occurred in an asymmetrical fashion.

In contrast to the stem cell-like O-2A^{adult} progenitor cells, O-2A^{perinatal} progenitor cells appear to be true progenitor cells, committed to differentiate within a limited time period, both *in vitro* and *in vivo*. Single O-2A^{perinatal} progenitor cells derived from P0 to P7 optic nerves and grown in microwells in Astro-CM or at low density on monolayers of cortical astrocytes normally divide ≤ 8 times before all cells in the colony differentiate clonally and synchronously into oligodendrocytes (Temple and Raff, 1986; Wren et al., 1992). A small number of col-

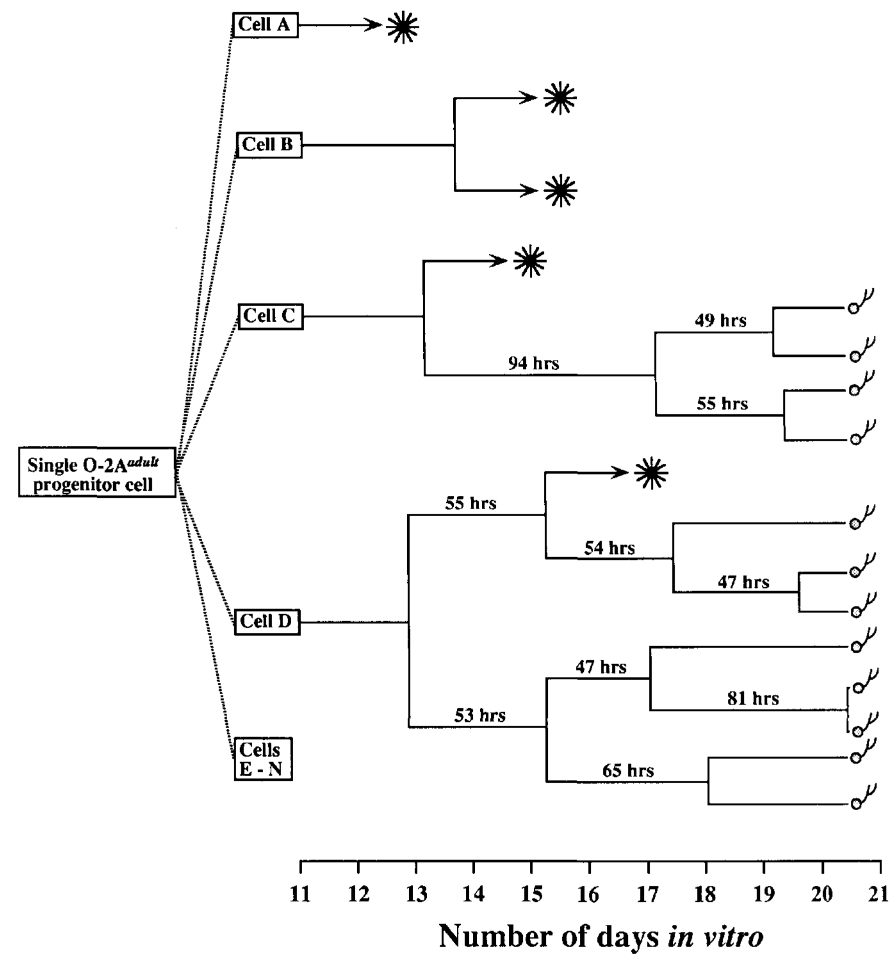

FIG. 9-3. Direct visualization of the asymmetric mode of division and differentiation of O-2A^{adult} progenitor cells grown on cortical astrocytes. Adult optic nerve cells were plated at low density on monolayers of cortical astrocytes (see Wolswijk and Noble, 1989). A colony generated by a single O-2A^{adult} progenitor cells was initially followed on a daily basis using an inverted microscope. When this colony was followed further using time-lapse cinemicroscopy, it was found that the 14 cells that were present in the O-2A^{adult} progenitor colony at the start of the filming period (cells *A–N*) had different fates (only the fate of cells *A–D* are shown). For example, *Cell A* adopted a multipolar oligodendrocyte-like morphology shortly after the start of the filming period, while *Cell B* divided once and both of its progeny cells acquired an oligodendrocyte-like morphology during the filming period. *Cell C* and *Cell D* generated many more progeny cells and some of these were still proliferating at the end of the filming period. Both cells also generated oligodendrocyte-like cells, and this occurred in an asymmetrical fashion. Thus, these results provide direct evidence that an O-2A^{adult} progenitor cell can generate oligodendrocytes and O-2A^{adult} progenitor cells in an asymmetrical manner. At the end of the filming period, this particular O-2A^{adult} progenitor colony contained 31 O-2A^{adult} progenitor cells and 15 oligodendrocyte-like cells. To illustrate the slow division rate of O-2A^{adult} progenitor cells grown in the presence of cortical astrocyte-derived factor(s) (Wolswijk and Noble, 1989), the cell cycle time of the various O-2A^{adult} progenitor cells in this family have been indicated.

onies generated by single O-2A^{perinatal} progenitor cells continue to expand following the appearance of oligodendrocytes (Temple and Raff, 1986; Wren et al., 1992), but such colonies may have generated O-2A^{adult} progenitor cells. Thus, O-2A^{adult} and O-2A^{perinatal} progenitor cells also differ in the manner these cells generate oligodendrocytes *in vitro:* most proliferating O-2A^{perinatal} progenitor cells differentiate into oligodendrocytes in a clonal fashion, while proliferating O-2A^{adult} progenitor cells predominantly generate oligodendrocytes in an asymmetrical manner (Table 9-1).

REPAIR PHENOTYPE OF O-2A^{adult} PROGENITOR CELLS

The presence of a population of oligodendrocyte progenitor cells in the adult CNS suggests that these cells may play an important role in the replenishment of the oligodendrocyte population following demyelinating damage, possibly in addition to mature oligodendrocytes (see later). This view is supported by two observations: First, cells with the antigenic characteristics of O-2A^{adult} progenitor cells grown *in vitro* have been shown to incorporate [^{3}H]thymidine and/or increase in number during the recovery process from demyelinating damage (Godfraind et al., 1989; Carrol et al., 1990). Second, the oligodendrocyte lineage cells that proliferate in response to experimentally-induced demyelination (Ludwin, 1979, 1984; Aranella and Herndon, 1984; Carrol et al., 1990; Rodriguez et al., 1991) and those that are present at the edges of demyelinating lesions in patients suffering from the most common human demyelinating disease multiple sclerosis (Raine et al., 1981) are ultrastructurally similar to O-2A^{adult} progenitor cells grown *in vitro* (Wolswijk et al., 1991a).

If the slowly dividing, stem cell-like O-2A^{adult} progenitor cells replenish the oligodendrocyte population following demyelinating damage, these cells may then also express another property of stem cells, that is, the ability to generate rapidly large numbers of progeny cells (Hall and Watt, 1989; Potten and Loeffler, 1990). Moreover, if O-2A^{adult} progenitor cells are involved in damage repair, substances involved in stimulating the division of O-2A^{adult} progenitor cells must be expressed or released following injury.

Several molecules present in lesion sites could trigger the increased proliferation of oligodendrocyte lineage cells in response to demyelinating damage, including cytokines secreted by reactive astrocytes, inflammatory cells or microglia, myelin breakdown products, and components present on demyelinated axons. However, due to the complexity of the *in vivo* situation, it is virtually impossible to determine which factors promote regeneration of the oligodendrocyte population, which factors hamper this, and which factors have no effect. Therefore, recent studies on O-2A^{adult} progenitor cells have been concerned with determining whether some of the factors in lesion sites are capable of inducing rapid division in O-2A^{adult} progenitor cells grown *in vitro*.

A factor that both appears to be expressed at increased levels following injury to the adult central nervous system (Finkelstein et al., 1988; Logan, 1988, 1990; Nieto-Sampedro et al., 1988; Eckenstein et al., 1991; Gómez-Pinilla et al., 1992; Logan et al., 1992) and is capable of increasing the rate of division of O-2A^{adult} progenitor cells grown *in vitro* is basic fibroblast growth factor (bFGF) (Wolswijk and Noble, 1992). Time-lapse cinemicroscopy studies have shown that O-2A^{adult} progenitor cells grown in bFGF have significantly shorter cell cycle times than those cultured in PDGF or in the presence of cortical astrocytes (Wolswijk and Noble, 1992). In addition, bFGF also almost completely prevents the differentiation of O-2A^{adult} progenitor cells into oligodendrocytes. The effects of bFGF on O-2A^{adult} progenitor cells appear to be direct, as such cells bind both radiolabeled bFGF and anti-FGF receptor antibodies (Wolswijk and Noble, 1992).

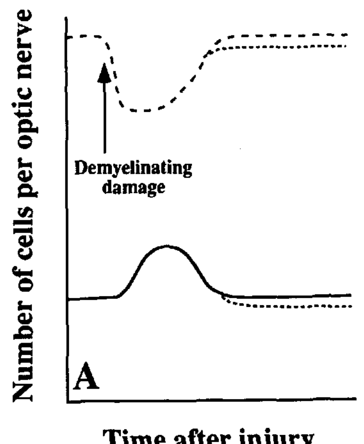
O-2A^{adult} progenitor cells exposed to bFGF can be induced to divide even more rapidly if they are also exposed to PDGF (Wolswijk and Noble, 1992). Moreover, many O-2A^{adult} progenitor cells grown in both PDGF and bFGF also express other characteristics of O-2A^{perinatal} progenitor cells, such as high rates of migration, bipolar morphology, and O4$^-$vimentin$^+$ antigenic phenotype (Wolswijk and Noble, 1992). Thus, cooperation between PDGF and bFGF converts many slowly dividing O-2A^{adult} progenitor cells to rapidly dividing cells with characteristics of O-2A^{perinatal} progenitor cells.

The effects of bFGF on the properties of O-2A^{adult} progenitor cells appear to be transient and bFGF does not induce rapid division and migration in all O-2A^{adult} progenitor cells (Wolswijk and Noble, 1992). However, as long as cultures are exposed to bFGF, O-2A^{adult} progenitor cells are prevented from differentiating into oligodendrocytes, even after 3 months of exposure (Wolswijk and Noble, 1992; G. Wolswijk, unpublished observations). The transient nature of the effect of bFGF on O-2A^{adult} progenitor cells could reflect intrinsic limitations on the growth of these cells, or it is possible that O-2A^{adult} progenitor cells need the presence of additional factor(s) to continue expressing an O-2A^{perinatal} progenitor-like phenotype.

If the pattern of cellular behavior expressed by O-2A^{adult} progenitor cells exposed to bFGF *in vitro* is duplicated *in vivo* following demyelinating damage (Figure 9-4), it would allow rapid increases in the number of O-2A^{adult} progenitor cells [as observed, for example, in lesions of animals recovering from experimentally-induced demyelination (Godfraind et al., 1989; Carrol et al., 1990)]. Subsequent differentiation of O-2A^{adult} progenitor cells into oligodendrocytes, followed by re-ensheathement of the denuded axons could then restore proper impulse conduction leading to recovery of function. Consistent with the hypothesis that bFGF may be involved in the increased generation of O-2A^{adult} progenitor cells *in vivo* are the findings that mechanically-induced injury to the adult central nervous system is associated with transient increases in the levels of bFGF, PDGF and their mRNAs (Finklestein et al., 1988; Logan, 1988, 1990; Nieto-Sampedro et al., 1988; Eckenstein et al., 1991; Gómez-Pinilla et al., 1992; Logan et al., 1992; Lotan and Schwarz, 1992). However, it is not yet known whether demyelinating damage is associated with increases in the levels of these two growth factors, either in experimental models of demyelinating diseases or in patients with multiple sclerosis.

The cellular and molecular mechanisms that underlie regenerative events in the oligodendrocyte lineage of the adult central nervous system suggest the following hypothesis (see Figures 9-4 and 9-5). PDGF is important in controlling the proliferation, migration, and differentiation of O-2A^{adult} progenitor cells in the healthy adult central nervous system. O-2A^{adult} progenitor cells in the normal adult brain either do not see bFGF or are exposed to only very low concentrations of bFGF. Following demyelinating damage, O-2A^{adult} progenitor cells in lesion sites are now exposed to much higher concentrations of PDGF and bFGF, resulting in the expression of a *repair* phenotype by many O-2A^{adult} progenitor cells. When the levels of bFGF (and PDGF) have gone down again, many O-2A^{adult} progenitor cells stop dividing and generate the oligodendrocytes that are needed to repair demyelinated lesions. Basic FGF in lesion sites may also induce division in oligodendrocytes that have survived demyelinating damage or in newly generated oligodendrocytes, as *in vitro* studies have suggested that bFGF is a mitogen for oligodendrocytes (see later).

The increased levels of PDGF seen following injury may have an additional function with regards to the generation of new oligodendrocytes in response to demyelinating damage. Studies by Barres



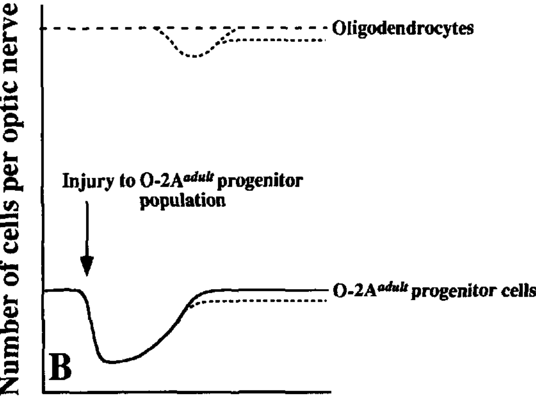


FIG. 9-4. Model for the regenerative events that may occur in the O-2A lineage of the adult central nervous system following damage to the oligodendrocyte population or O-2A^{adult} progenitor population. (A) Demyelinating damage to the adult central nervous system induces the expression of a rapidly dividing phenotype in O-2A^{adult} progenitor cells, resulting in a local increase in the number of O-2A^{adult} progenitor cells. When sufficient new O-2A^{adult} progenitor cells have been generated, these cells differentiate into oligodendrocytes, which in turn remyelinate the denuded axons. It theoretically is possible that demyelinating damage may result in a permanent reduction in the number of O-2A^{adult} progenitor cells (and oligodendrocytes). (B) There is evidence that also the O-2A^{adult} progenitor population is replenished when this population is damaged specifically. Studies by Van der Maazen and colleagues have indicated that x-ray irradiation of the adult optic nerve *in vivo* results in a dramatic decrease in the number of O-2A^{adult} progenitor cells that can be recovered from irradiated adult optic nerves shortly following irradiation (Van der Maazen et al., 1992). With time the number of O-2A^{adult} progenitor cells that can be isolated from irradiated optic nerves increases, but even low doses of x-ray irradiation cause a permanent reduction in the number of O-2A^{adult} progenitor cells (Van der Maazen et al., 1992). This in turn could then theoretically also cause a temporary or permanent reduction in the number of oligodendrocytes. Consistent with this hypothesis is the observation that demyelination can be one of the side effects of x-ray irradiation *in vivo* (Van der Kogel, 1980).

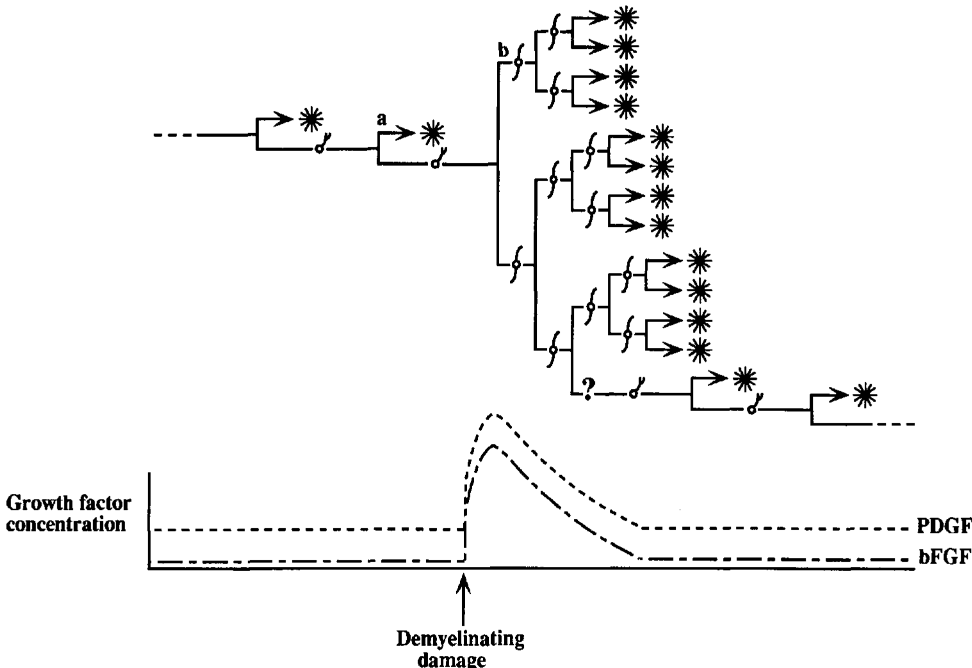

FIG. 9-5. A model of the generation of large numbers of oligodendrocytes by O-2A^{adult} progenitor cells in response to demyelinating damage. In the healthy adult central nervous system, O-2A^{adult} progenitor cells are exposed to PDGF (and possibly low levels of bFGF) and generate oligodendrocytes in an asymmetrical fashion and at a slow rate [To simplify the model, each O-2A^{adult} progenitor cell was assumed to generate only one oligodendrocyte and one further O-2A^{adult} progenitor cell at each division]. Following injury to the central nervous system, the levels of PDGF and bFGF are increased transiently. As a result, O-2A^{adult} progenitor cells are exposed to much higher concentrations of bFGF and PDGF and this elicits the expression of a *repair* phenotype in many O-2A^{adult} progenitor cells: instead of differentiating, O-2A^{adult} progenitor cells continue to divide and do so with much shorter cell cycles than when these cells are exposed only to PDGF. When the levels of PDGF and bFGF have gone down again, the O-2A^{adult} progenitor cells that kept on dividing in response to PbF differentiate and generate the oligodendrocytes that are needed to repair demyelinated lesions. For example, *Cell b*, in this model, generates four oligodendrocytes instead of the one oligodendrocyte generated by *Cell a*. The increased levels of PDGF may also be important in increasing the survival of newly generated oligodendrocytes (see Barres et al. 1992). It is not yet known whether all the members of an O-2A^{adult} progenitor family following transient exposure to PbF differentiate into oligodendrocytes or whether some cells remain as O-2A^{adult} progenitor cells.

and colleagues have suggested that about 50% of newly formed oligodendrocytes in the optic nerves of developing animals die due to limiting amounts of PDGF (Barres et al., 1992). If 50% of the newly generated oligodendrocytes in the adult central nervous system also normally die, increased survival of oligodendrocytes as a result of local increases in the concentrations of PDGF in itself could significantly increase the numbers of oligodendrocytes available to repair demyelinating lesions.

THE SIGNIFICANCE OF THE DEVELOPMENTAL TRANSITION IN O-2A PROGENITOR TYPE

The properties expressed by O-2A^{perinatal} progenitor cells *in vitro* are consistent with the expected physiological requirements of the developing central nervous system. For example, the rapid rate of division of O-2A^{perinatal} progenitor cells grown *in vitro* is consistent with evidence indicating that O-2A lineage cells are generated rapidly during development of the rat optic nerve (Skoff et al., 1976a, 1976b; Miller et al., 1985; Barres et al., 1992). Furthermore, the highly motile nature of O-2A^{perinatal} progenitor cells is in agreement with suggestions that these cells migrate from germinal zones into several regions of the developing central nervous system such as optic nerve (Small et al., 1987), cerebellum (Wolswijk, 1995), and spinal cord (Warf et al., 1991). Finally, the observation that O-2A^{perinatal} progenitor families either differentiate clonally into oligodendrocytes or generate O-2A^{adult} progenitor cells is consistent with the finding that the O-2A^{perinatal} progenitor population disappears from the developing optic nerve (see Figure 9-2).

The *in vitro* properties of O-2A^{adult} progenitor cells are also consistent with a number of *in vivo* obser-

vations. First, there appears to be only a modest production of oligodendrocytes in the adult brain (McCarthy and Leblond, 1988), which is consistent with the slow rate of division and differentiation of O-2A^{adult} progenitor cells. Second, the observation that demyelinating damage appears to be associated with increased division in the oligodendrocyte lineage is compatible with the ability of O-2A^{adult} progenitor cells to express a rapidly dividing phenotype. Moreover, it is reasonable to propose that the normal mature brain has a reduced requirement for precursor migration, which is in agreement with the slow migratory behavior of O-2A^{adult} progenitor cells *in vitro*. However, when O-2A^{adult} progenitor cells are induced to undergo rapid division, these cells acquire the ability to migrate rapidly and this increased migratory capacity may be relevant to repair of demyelinated lesions.

PROLIFERATION OF OLIGODENDROCYTES AND RECOVERY FROM DEMYELINATING DAMAGE

In addition to the generation of new oligodendrocytes by O-2A^{adult} progenitor cells in response to demyelinating damage, proliferation of oligodendrocytes may be important in the recovery process. Uptake of [^{3}H]thymidine by oligodendrocytes has been observed *in vivo* after experimentally-induced demyelination (Aranella and Herndon, 1984) and after mechanical trauma to the adult brain (Ludwin, 1984). In addition, Ludwin and Bakker (1988) found that even myelinating oligodendrocytes incorporated radiolabeled thymidine after wounding of the cerebral cortex of adult mice. However, only a comparatively small proportion of oligodendrocytes were radiolabeled in these studies, suggesting that their contribution to the generation of new oligodendrocytes may be relatively small. It is not known what factor(s) induce division in oligodendrocytes *in vivo*.

The ability of oligodendrocytes to divide has been demonstrated directly in tissue culture experiments. For example, oligodendrocytes incorporate [^{3}H]thymidine in response to bFGF (Eccleston and Silberberg, 1985; Saneto and DeVellis, 1985; Bögler et al., 1990; Wolswijk and Noble, 1992), when cocultured with dorsal root ganglion cells (Wood and Bunge, 1986, 1991), when exposed to axollemal-enriched fractions (Chen and DeVries, 1989) and when grown on an extracellular matrix (Ovadia et al., 1984). However, the vast majority of the oligodendrocytes that are induced to divide by exposure to bFGF and those that proliferate when cocultured with dorsal root ganglion neurons do not express myelin basic protein (MBP) (Wood and Bunge, 1986, 1991; D. Wren and M. Noble, unpublished observations), a marker for mature, myelinating oligodendrocytes. These observations suggest that only a population of immature oligodendrocytes is proliferatively active, at least *in vitro*.

FACTORS LIMITING MYELIN REPAIR

There are several factors that may hamper regeneration in the oligodendrocyte lineage, some of which may be relevant to the ultimate failure of myelin repair in patients suffering from multiple sclerosis (McDonald and Silberberg, 1986). While there is some evidence for myelin repair at the edges of multiple sclerosis lesions (Prineas and Connel, 1979; Raine et al., 1981; Prineas et al., 1989), the centers of old lesions of "plaques" are often virtually completely devoid of oligodendrocytes, and bare axons are surrounded instead by astrocytic processes. Very little is known about why remyelination is generally unsuccessful in multiple sclerosis patients or about the cause of the initial destruction of oligodendrocytes. Although great caution should be taken with extrapolating tissue culture data obtained with rat cells to humans, it is intriguing that *in vitro* studies have revealed striking consistencies between the properties of O-2A^{adult} progenitor cells and certain features of multiple sclerosis.

Exposure of O-2A^{adult} progenitor cells (and oligodendrocytes) to a factor that specifically eliminates these cells *in vivo* would theoretically contribute to the formation of lesions that remain chronically demyelinated (see Figure 9-4), such as those found in multiple sclerosis patients. An example of such a possibility has come from *in vitro* studies that have indicated that O-2A^{adult} progenitor cells share with oligodendrocytes the ability to bind and activate complement in the absence of antibody, resulting in their destruction (Wren and Noble, 1989). This sensitivity to complement appears to be a specific property of oligodendrocytes and O-2A^{adult} progenitor cells, as several other cell types, including O-2A^{perinatal} progenitor cells, do not express this property (Scolding et al., 1989; Wren and Noble, 1989) (see Table 9-1). While it is not known whether complement-mediated destruction of O-2A^{adult} progenitor cells and oligodendrocytes plays a role in the formation of chronically demyelinated lesions, complement does appear to be activated in areas of myelin breakdown (Compston et al., 1991).

It appears that both the number of O-2A^{adult} progenitor cells that can be obtained from one pair of adult optic nerves and the number of cells O-2A^{adult}

progenitor cells give rise to *in vitro* when stimulated to divide by cortical astrocytes decreases with age of the donor animal (Wolswijk and Noble, 1989, 1992; Van der Maazen et al., 1992; G. Wolswijk, unpublished observations). These data suggest that with increasing age fewer O-2A^{adult} progenitor cells may be available to generate the oligodendrocytes that are needed to repair demyelinating damage, thereby reducing the ability of the adult central nervous system to recover from demyelinating damage. This is complemented by two *in vivo* observations. First, the potential for recovery from optic neuritis, a human demyelinating disease of the optic nerve, appears to decrease with age (McDonald, 1983; Kriss et al., 1988). Second, ethidium bromide-induced demyelinated lesions in spinal cord white matter of adult rats are repaired less successfully in rats that are over 12 months old as compared to 5-month-old rats (Gilson and Blakemore, 1993).

THE *IN VIVO* IDENTIFICATION OF O-2A^{adult} PROGENITOR CELLS

To study the role of O-2A^{adult} progenitor cells in the repair of demyelinated lesions *in vivo*, the identification of such cells in sections of adult central nervous system tissue is essential. Several potential markers for O-2A^{adult} progenitor cells *in vivo* have been identified. For example, Pringle and colleagues have suggested that O-2A^{adult} progenitor cells in sections of adult optic nerve can be identified on the basis of their expression of the PDGF α-receptor (Pringle et al., 1992), while Fulton and colleagues have suggested that glutamate receptor-linked cation channels of the quisqualate-kainate type may be expressed by only O-2A^{adult} progenitor cells in the adult central nervous system (Fulton et al., 1992). Another study has suggested that O-2A^{adult} progenitor cells in the adult cerebellum express the NG2 chondroitin-sulfate proteoglycan (Levine et al., 1993; Levine 1994).

A recent study has examined whether antibodies to the ganglioside G_{D3} can be used to identify O-2A^{adult} progenitor cells in sections of adult central nervous system tissue, as studies on the developing central nervous system had suggested that O-2A^{perinatal} progenitor cells are G_{D3}^+ *in vivo* (e.g., Reynolds and Wilkin, 1988). Although O-2A^{adult} progenitor cells express G_{D3} in tissue culture, all G_{D3}^+ cells in sections of adult optic nerve are ramified microglia (Wolswijk, 1994). Moreover, a re-examination of the identity of G_{D3}^- expressing cells in the developing cerebellum has revealed that all strongly G_{D3}^+ cells are either amoeboid microglia or ramified microglia and not O-2A^{perinatal} progenitor cells (Wolswijk, 1995), as suggested previously (e.g., Reynolds and Wilkin, 1988). Thus, these results suggest that the identification of a cell as an O-2A^{adult} progenitor cell (or any other cell type) on the basis of the expression of a single marker may not be entirely reliable. Therefore, it is of paramount importance to re-examine the studies that have identified markers for O-2A^{adult} progenitor to verify that the cells that express these markers *in vivo* are indeed O-2A^{adult} progenitor cells.

CONCLUSIONS

A number of conclusions can be drawn from the *in vitro* studies on O-2A^{perinatal} and O-2A^{adult} progenitor cells. *First*, the developing and adult central nervous system each contain a population of O-2A progenitor cells with properties that appear to be consistent with the expected physiological requirements of their respective environments. *Second*, O-2A^{perinatal} and O-2A^{adult} progenitor cells belong to the same glial lineage. *Third*, O-2A^{perinatal} progenitor cells are true progenitor cells, while O-2A^{adult} progenitor cells express properties of stem cells. *Fourth*, cooperation between PDGF and bFGF, two factors that appear to be upregulated and/or released following central nervous system injury, induces a *repair* phenotype in O-2A^{adult} progenitor cells. *Fifth*, studies on O-2A^{adult} progenitor cells have provided clues as to why remyelination may be less effective in adults with multiple sclerosis than in children with similar lesions. *Sixth* and finally, as there also appear to be differences between *perinatal* and *adult* precursor populations in other lineages of multicellular organisms (e.g., Metcalf and Moore, 1971; Wood et al. 1985; Anderson, 1989; Stockdale, 1992), the studies on O-2A^{perinatal} and O-2A^{adult} progenitor cells could serve as a model to provide useful strategies for the analysis of developmental transitions in precursor populations in such lineages.

The studies on O-2A^{adult} progenitor cells have been funded by generous grants from the Multiple Sclerosis Society and Medical Research Council of Great Britain. We wish to thank the colleagues with whom we have had many helpful discussions during the course of the work, in particular Damian Wren and Ian McDonald. We also thank Alan Entwistle for critically reading the manuscript.

10 Development of microglia

SERGEY FEDOROFF

Microglia are a significant component of the fabric of the central nervous system (CNS). They comprise 5 to 12% of the cells of the central nervous system and are arranged strategically and in an orderly topographical manner (Perry et al., 1985; Lawson et al., 1990). Recent investigations point to a pivotal role for microglia, not only in the defense mechanism of the CNS, but also in its steady-state condition (Graeber and Streit, 1990; Merrill, 1991, 1992; Fedoroff et al., 1993). Despite the important role of microglia in the neuron-glia functional loop, their origin, lineage, and mode of differentiation are still cloaked in mystery and beset with misconceptions. A longstanding controversy centers around the origin of microglia: are they descendants of hemopoietic myeloid stem cells or, like other glia, do they form from neuroectoderm?

Early work on the subject is well summarized in a number of reviews: Rio Hortega (1932); Glees (1955); Kitamura (1973); Oehmichen (1978); Boya et al. (1979); Baldwin (1980); Fujita (1980); Fujita et al. (1981); Ling (1981); Polak et al. (1982); Jordan and Thomas (1988); Streit et al. (1988); Perry and Gordon (1991); Peters et al. (1991); Thomas (1992); Ling and Wong (1993); Theele and Streit (1993). The earlier studies were predominantly based on morphological observations using selective silver carbonate impregnation, electron microscopy, [^{3}H]TdR incorporation into the DNA of cells, and by "marking" phagocytic cells with colloidal carbon. More recent studies utilize chimeric animals in which hemopoietic cells carry an identifiable protein or DNA genetic marker, immunocytochemistry, and developmental and functional analysis in tissue culture.

GENERAL CONSIDERATIONS

A popular view is that microglia form from hemopoietic monocytes; therefore, this chapter first reviews the development of the hemopoietic system in general, the development of monocytes/macrophages, and more recent work relevant to the understanding of the development and cell lineage of microglia. These topics are closely interrelated, and, to keep the origin of microglia in focus while discussing them, three theoretical possibilities for microglia formation in the CNS are described and their feasibility considered.

Colonization of the Central Nervous System by Hemopoietic Stem Cells During Ontogeny

In this possible situation, the colonizing cells would be hemopoietic stem cells that can self-replicate and be able to provide differentiating cells throughout the life of the animal to maintain a constant number of microglia in the CNS. Such stem cells would have to enter the CNS during the early stages of embryonic development and either be dispersed throughout the CNS or be located in discrete "germinal centers." Hemopoietic centers that produce the various blood cells are not known to exist in the CNS, and therefore it would have to be assumed that the parenchyma of the CNS is compatible with hemopoietic stem cell survival but inhibits the stem cells from forming hemopoietic cells other than in the monoblast-monocyte lineage. If the colonizing hemopoietic cells were already restricted to the monoblast-monocyte lineage before they colonized the CNS, such cells would be expected to have a limited degree of proliferation and would be considerably modified phenotypically from their counterparts in the bone marrow.

The self-replicating hemopoietic stem cells in the CNS would have to produce a number of transitional forms ranging from monoblasts to monocytes and then from monocytes to microglia. As microglia populate the entire CNS in an orderly manner, they would have to migrate extensively to find their proper location. There would also have to be a regulatory mechanism for the turnover rate of microglia under steady-state conditions to maintain constant numbers of microglia in the CNS and under pathological conditions to rapidly increase the numbers of microglia.

Infiltration of the Central Nervous System by Hemopoietic Cells Throughout the Life of the Animal

In this scenario the self-replicating stem cells would be located outside the CNS, most likely in the bone marrow, and their progeny (monocytes) would infiltrate the CNS throughout the life of the animal. The infiltrating cells either would have limited ability to divide and produce a number of transitional forms in the CNS that would eventually form microglia or would transform directly into microglia, as monocytes transform into macrophages in the body tissues. Under this possibility, as in the previous one, the immature cells would have to be migratory. The regulating mechanism for microglia turnover would have to be responsible for the normal steady-state condition in the hemopoietic tissue. From this it follows that deviation from the normal steady state condition in the hemopoietic tissue would reflect the turnover of microglia within the CNS.

Development of Microglia from Neuroectoderm

This possibility would assume that microglia originate from a common glia stem cell, the glioblast, in the ventricular and later, in the subventricular zone of the developing neural tube. The microglia lineage would be a branch of the glia lineage and precursor cells responsible for the turnover rate of astroglia and oligodendroglia throughout the life of the animal might also be responsible for the turnover rate of microglia.

These are the three most obvious possibilities for the origin of microglia. We now examine pertinent available information to reach some conclusions as to which possibilities are tenable.

DEVELOPMENT OF THE HEMOPOIETIC SYSTEM

In mammals, the ancestral hemopoietic stem cells form extraembryonically in the wall of the yolk sac (Metcalf and Moore, 1971). There are indications, however, that the ancestral hemopoietic stem cells may have multiple sites of origin. It has been well demonstrated that in the chick, ancestral hemopoietic stem cells form independently, intraembryonically, in the dorsal wall of the thoracic aorta as well as in the yolk sac. Similar observations have been made in mice (Smith and Glomski, 1982). From both sites the stem cells colonize other hemopoietic centers (Dieterlen-Lièvre, 1987; Cormier and Dieterlen-Lièvre, 1988; Dieterlen-Lièvre et al., 1988). Ogawa et al. (1988) suggested that stem cells producing B lymphocytes arise *de novo* within the embryo. B-lymphocytes and myeloid cells arise from the same primitive stem cell; it therefore follows that some pluripotent stem cells must originate intraembryonically. Further support for this notion was recently provided by Cumano et al. (1992). They unequivocally demonstrated that in the livers of mice at day 12 of gestation, bipotential cells are present that give rise to B lymphocytes and macrophages. This observation is of great significance because it indicates that macrophages can form from several lineages, not only via the monoblast-monocyte lineage.

In mice, the first signs of erythropoiesis are seen at Theiler stage 11 (day 7 of gestation) and in man on days 21 to 28 (Metcalf and Moore, 1971; Theiler, 1972). Although the stem cells in the yolk sac produce only nucleated erythrocytes, they have the potential to form cells of all hemopoietic cell lineages. This has been verified by analyzing the stem cells in tissue cultures and/or irradiated animals (Moore and Metcalf, 1970; Metcalf and Moore, 1971; Perah and Feldman, 1977; Migliaccio et al., 1986). When the cardiac tubes begin to contract and the blood islands of the yolk sac become connected to the intraembryonic blood vascular network, the stem cells from the yolk sac enter the circulation on day 11 of gestation in mice and at 5 weeks postconception in humans (Metcalf and Moore, 1971; Migliaccio et al., 1986). They colonize the mesodermal hepatic rudiment where enucleated erythrocytes are beginning to be produced. At first only enucleated erythropoiesis takes place in the hepatic rudiment but later, macrophages and granulomonocytic elements appear. It has been suggested that at this stage some macrophages may be forming from mesenchymal cells and/or granulomonocytic stem cells, which preferentially differentiate in the monocyte pathway (Migliaccio et al., 1986).

The mesenchymal spleen rudiment in mice appears on day 13 of gestation and hemopoietic stem cells from the liver colonize the spleen and begin active erythropoiesis in the spleen at day 15. In humans the spleen is populated by stem cells at 19 weeks (Hann et al., 1983). By day 17, in mice, granulopoiesis predominates. The spleen is a unique hemopoietic organ in which every hemopoietic cell type is produced. It has been estimated that on day 4 postnatal, mouse spleen contains about 50% of the total body population of hemopoietic stem cells (Metcalf and Moore, 1971).

The bone shafts in mice are cartilaginous at day 15 of gestation. On day 17, marrow cavities appear and by day 17–18 they are colonized by circulating stem cells from the liver and spleen. Erythropoiesis, however, does not begin before birth. In human embryos, hemopoiesis begins around 15–16 weeks (Hann et al., 1983) or according to Metcalf and

Moore (1971), at the 20th week of gestation. Once the bone marrow has become colonized by hemopoietic stem cells, further development proceeds by the expansion of the stem cell population rather than by recruitment of stem cells from liver and spleen.

DEVELOPMENT OF MONOCYTOPOIESIS

Several types of multipotential, self-replicating, hemopoietic stem cells generate a progeny of eight major lineages of hemopoietic cells that form erythrocytes, megakarocytes, monocytes, granulocytes, basophils, eosinophils, T lymphocytes, and B lymphocytes. The stem cell progeny progress along various pathways of differentiation in a rather heterogeneous fashion but always toward more and more committed cells with restricted developmental potential and less and less proliferative capacity. The monoblast-monocyte-macrophage lineage begins with myeloid-lymphoid stem cells, then pluripotential myeloid stem cells, followed by granulocyte-macrophage colony-forming cells, then macrophage colony-forming cells which differentiate into monoblasts, promonocytes, and finally monocytes (Novak et al., 1989). The number of cell generations between the ancestral stem cell and the generation of the final nondividing monocyte is not known. Monocytes remain in the bone marrow for probably less than 24 hours and then enter randomly into the blood circulation. There they marginate by attaching to the endothelium and then enter various body tissues, at different rates (van Furth, 1988). The half-time of monocytes in the blood circulation has been calculated as 17.4 hours (van Furth et al., 1973). Table 10-1 shows the percentage of monocytes leaving the circulation in different tissues and the rate of influx.

Formation of Macrophages During Fetal Development

Specific cell markers are available to identify monocytes-macrophages. The marker most commonly used is the F4/80 antibody to an unknown antigen (Austyn and Gordon, 1981), although recently it has been shown that eosinophils also bind antibody to F4/80 (McGarry and Stewart, 1991). Other markers include the Fc receptor for immunoglobulins, the CR3 receptor for complement (Unkeless and Wright, 1988), and α-D-galactose residues, which are recognized by *Griffonia simplicifolia* isolectin-B_4 (GSA I-B_4) (Streit et al., 1985; Streit, 1990). Thus monocyte-macrophage formation during embryonic development is defined in terms of these markers, mainly the expression of F4/80 antigen (Perry et al., 1985; Lawson et al., 1990; Gordon et al., 1992). Monocyte-macrophage development closely follows the development of hemopoiesis; however, it is curious that some F4/80-positive cells can be found in hemopoietic sites such as liver, spleen, and bone marrow, before hemopoiesis is seen (Morris et al., 1991). In mice, the F4/80 positive cells are clearly seen in the yolk sac between days 9 and 10 of gestation (Gordon et al., 1992), in liver at day 10–11, spleen at day 12, and bone marrow at day 16. In liver, spleen, and bone marrow there is a definite intimate association between monocytes-macrophages and erythroblasts (Morris et al., 1991). The development of macrophages is not, however, limited to the hemopoietic sites. They are found around the developing neuroectoderm and mesenchyme of lungs on day 12, thymus on day 14, and gut on day 15 (Morris et al., 1991). Macrophages are phagocytic but, contrary to the state in adult animals, proliferate profusely, and are found outside the blood vessels between mesenchymal cells. As the organs develop, macrophages become resident cells of the connective tissue of the organs (Morris et al., 1991).

Formation of Macrophages in Adult Tissues

Macrophages originate in adult body tissues and organ cavities from the monocytes that enter from the bone marrow. In the tissues, the monocytes increase in size and become ameboid. Their Golgi apparatuses enlarge and become the site of formation of

TABLE 10-1. *Kinetic Parameters of Macrophages at Various Sites*

Site	Monocytes leaving the circulation (%)	Rate of monocyte influx[a] ($\times 10^3$/h)	Rate of local production[a] ($\times 10^3$/h)	Mean turnover time of macrophages (days)
Liver	71.8	93.3 (92%)	7.7 (8%)	3.8
Spleen	24.7	15.2 (55%)	12.2 (45%)	6.0
Lung	14.7	9.1 (67%)	4.4 (33%)	6.0
Peritoneal cavity	6.7	4.2 (61%)	2.7 (39%)	14.9

[a]The percentages in parentheses give the relative contribution made by influx and local production to the composition of the respective macrophage populations.

lysozyme and endocytotic activity increases. The transitional forms between monocytes and macrophages are difficult to define and all are based primarily on morphological characteristics. Although the majority of macrophages form from monocytes, there is evidence that certain numbers of macrophages form locally (Table 10-1), probably by division of preexisting macrophages or from other progenitor cells (Cormier and Dieterlen-Liévre, 1988; Ogawa et al., 1988; Cumano et al., 1992). The fate of macrophages is not known. However, there is no steady accumulation of macrophages in any tissues or organ cavities in the normal steady-state condition. There is some evidence that macrophages can translocate to other tissues or to regional lymph nodes where they die (van Furth et al., 1980). It is important to note that the estimated turnover time of body macrophages varies according to the tissue they are in and ranges from 3.8 days in the liver to 14.9 days in peritoneal cavity (van Furth, 1988) (Table 10-1).

The complex path of macrophage development and the various cell compartments evolved are in dynamic equilibrium. Hemopoiesis leading to the formation of mature blood cells, including macrophages, is regulated by a number of mechanisms. One depends on stromal cells (mesenchymal cell derivatives), which interact with hemopoietic cells at short range through trophic factors embedded in the stromal cell membranes or through soluble factors that signal the proximal cells (Dexter, 1982; Quesenberry et al., 1989). In addition, there are at least 16 distinct factors, (cytokines) produced by a variety of cells in hemopoietic sites as well as in other tissues. These trophic factors act on hemopoiesis by paracrine, autocrine, intracrine, juxtacrine, or signaling in synergistic, additive or inhibitory fashion. The interested reader is referred to the following reviews on this subject: Metcalf (1988, 1991); Orlic (1989); and Hamilton (1993).

ORIGIN OF THE CONCEPT OF THE MONONUCLEAR PHAGOCYTE SYSTEM

The term "macrophage" was coined by Metchnikoff (1892) to denote cells capable of ingesting large particles, including whole cells such as erythrocytes, spermatozoa, and the like, and to contrast them with polynuclear lymphocytes, which he termed "microphages" because they took up smaller particles such as bacteria. He recognized that macrophages in spleen, lymph nodes, and bone marrow have similar functions and that they are ameboid and in case of injury, surround the injured area or foreign body. He thought that such cells might serve in the defense of the organism against infections because they not only engulf but also rapidly kill and digest most invading microorganisms; he therefore introduced the term "macrophage system."

Aschoff (1924) modified and expanded the concept of a macrophage system. He grouped all cells that can take up vital dyes into the "reticuloendothelial system." He considered the uptake of vital dyes to be a test of phagocytosis and grouped cells in order according to the degree of dye uptake. He excluded endothelial cells and fibroblasts from the system because they take up little of the dyes. He included reticular cells of spleen and lymph nodes, reticuloendothelial cells of lymph and blood sinuses, including Kupffer cells, connective tissue histocytes, splenocytes, and monocytes. He pointed out that inclusion of cells in the reticuloendothelial system does not imply that they are identical; they may differ in their morphology, arrangement, and rate of uptake of foreign materials.

The practical significance of Aschoff's system and its heterogeneity was discussed in Leiden, Netherlands, during a conference on mononuclear phagocytes in 1949. It was felt that new knowledge of macrophage morphology, function, and kinetics makes it possible to group highly phagocytic mononuclear cells and their precursors into one system, the *mononuclear phagocyte system* (MPS) (van Furth et al., 1972).

A variety of experimental procedures have been used on normal animals and animals with acute or chronic inflammation, in lethally irradiated animals with or without bone marrow shielding, in radiation chimeras and parabiotic animals, using radioactive isotopes, chromosomes, or tissue antigens as stable markers to trace the cells. According to these studies, mononuclear phagocytes originate from precursor cells in the bone marrow, which are then transported by the peripheral blood as monocytes and eventually become tissue macrophages (van Furth et al., 1972, 1975). As a result the concept was developed that the mononuclear phagotype system is composed of cells related by similarities in morphology, function, and origin (van Furth et al., 1972, 1975).

The mononuclear phagocyte system includes monocytes and their precursor cells in the bone marrow, macrophages of the connective tissue, histiocytes, Kupffer cells of the liver, lung alveolar macrophages, free and fixed macrophages of lymph nodes, bone marrow macrophages, pleural and peritoneal cavity macrophages, osteoclasts, and microglia of the nervous system (van Furth, 1988). Microglia were included in the system with some reluctance. They were added because during the de-

velopment of the CNS, microglia cells are found only after the blood vessels have grown in (Andersen and Matthiessen, 1966), and in pathological processes, the accumulated mononuclear phagocytes supposedly including microglia originate from circulating monocytes (Konigsmark and Sidman, 1963; Kosunen et al., 1963; Waksman, 1965; Huntington and Terry, 1966; reviewed by van Furth, 1970; van Furth et al., 1972).

Indisputably, monocytes can infiltrate the CNS and have the potential to transform into macrophagelike cells (Meyermann et al., 1986; Wekerle et al., 1986; Hickey and Kimura, 1988; Hickey, 1991; Hickey et al., 1991; Hickey et al., 1992) and give rise to perivascular macrophages (Hickey and Kimura, 1988), but there is no convincing evidence that microglia in the parenchyma of the CNS form from monocytes (Choi, 1981; Matsumoto et al., 1985; Matsumoto and Ikuta, 1985; Schelper and Adrian, 1986; De Groot et al., 1992).

Despite efforts (van Furth et al., 1972, 1975) to unify the macrophages into a system of cells with common origin and function, the mononuclear phagocyte system represents a very heterogeneous population of cells (Gordon and Hirsch, 1982; Dijkstra et al., 1985; Nibbering et al., 1987; Perry and Gordon, 1987; van Furth, 1988; Keller et al., 1989; Oliver, 1990). The morphology of its cells varies greatly, depending on the tissue in which the cells are located and on their functional state. Even within the same tissue in normal steady-state conditions, the morphology of macrophages may differ. The antigenic characteristics vary in degree of expression and the frequency of cells expressing the antigen. Certain antigens may be absent in some macrophages and present in others (Walker, 1976; van Furth, 1988). Therefore, macrophages of each tissue must be characterized carefully; observations made with macrophages in one type of tissue do not necessarily apply to macrophages of another tissue. In tissue cultures, the morphology of macrophages can vary depending on the serum in the medium, concentration of bacterial wall lipopolysaccharide (endotoxin), and cytokines (e.g., CSF-1) (Graeber et al., 1989; Hao et al., 1990; Abd-El-Basset and Fedoroff, 1994).

There are, however, basic requirements for a cell to belong to the mononuclear phagocyte system (van Furth, 1980). These are as follows:

1. Morphological characteristics, including positive immunoreactivity with mononuclear phagocyte-specific antibodies, for example, F4/80, and the presence in the cytoplasm of such enzymes as nonspecific esterase, lysozyme, and peroxidase, which are demonstrable by histochemical and immunocytochemical methods.
2. Presence of Fc receptor.
3. Presence of CR3 receptor for complement.
4. Capability of Fc and CR3 receptors to mediate immunophagocytosis, and phagocytosis of opsinized bacteria.
5. Avid pinocytosis.

As a rule, not all of the mononuclear phagocytes are positive for all these criteria, but it is generally accepted that a cell must satisfy at least three of them before it can be considered to belong to the mononuclear phagocyte system (van Furth, 1988).

In order to make the point that cells that have common features and/or function do not necessarily have common ancestry, I would like to consider the dendritic cells. There is general hesitancy to include dendritic cells as full members of the mononuclear phagocyte system; instead, they are usually listed as belonging to the system—with a question mark (van Furth, 1988). The dendritic cells are present in most tissues of the body (see review by Fossum, 1989), although they are best known to occur in the lymphoid tissues and epidermis, where they are called Langerhans cells. Their common characteristics are that they express major histocompatibility complex (MHC) class II antigens, are antigen-presenting cells, are weakly phagocytic, and have veiled or dendritic morphology with a large amount of pale-staining cytoplasm. The Langerhans cells express Fc and CR3 receptors, and are F4/80-positive (Fossum, 1989; van Furth, 1988). Dendritic cells in human embryos have been found at 4 to 6 weeks of gestation together with monocytes and macrophages in the yolk sac (Janossy et al., 1986). They are disseminated from the yolk sac through all body tissues except cornea and brain (Hart and Fabre, 1981; Hofman et al., 1984). Dendritic cells are not found in embryonic or normal adult brains, but they do enter the brain from the blood circulation during allograft rejection (Lawrence et al., 1990).

During adult life dendritic cell precursor cells occur in the bone marrow where they proliferate. Dendritic cells are usually short lived in the tissues, although some may survive for several months (Fossum, 1989). They are renewed by cells from the bone marrow, although there is some evidence that Langerhans cells, especially, can replicate in tissues (Hashimoto and Tarnowski, 1968; Miyauchi and Hashimoto, 1987; review by Fossum, 1989). It has been estimated that 3 to 4% of Langerhans cells in the epidermis are in a cell cycle (Czernielewski et al., 1985). Thus, Langerhans cells are replenished from the bone marrow as well as locally in the epidermis.

During embryonic development dendritic cells are found in the same tissues, side by side with macrophages. This observation has been used to support the argument that dendritic cells belong to a separate cell lineage because it is not likely that the same environment would produce two phenotypically different cells stemming from the same progenitor cell (Fossum, 1989).

It is assumed that the development of hemopoietic cells is ordered in a hierarchical sequence, as mentioned previously in this chapter, starting with myeloid-lymphoid stem cells, pluripotential myeloid stem cells, granulocyte-monocyte colony forming cells (GM-CFCs), which give rise to macrophage-colony forming cells (M-CFCs) and granulocyte-colony forming cells (G-CFCs) (Novak et al., 1989). According to the mononuclear phagocyte system concept, the macrophages develop as terminally differentiated from M-CFCs, through a number of intermediate stages (van Furth, 1989). *In vitro* studies have indicated that the differentiation and function of M-CFCs is regulated by colony stimulating factor 1 (CSF-1) and the differentiation and function of G-CFCs by G-CSF. The differentiation of dendritic cells *in vitro,* however, is regulated by GM-CSF secreted by keratinocytes. CSF-1 and G-CSF have no effect on the differentiation of dendritic cells (Steinman, 1981; Witmer-Pack et al., 1987; Heufler et al., 1988; MacPherson et al., 1989; Markowicz and Englemen, 1990).

In vitro observations are supported by the study of mutant osteopetrotic *op/op* mice, which lack CSC-1 systemically (Wictor-Jedrzejczak et al., 1990) but produce normally GM-CSF, IL-1, IL-3, and IL-6 (Yoshida et al., 1990). In *op/op* mice the macrophage population is drastically decreased in all tissues, but to various degrees (Naito et al., 1991; Wictor-Jedrzejczak et al., 1992; Witmer-Pack et al., 1993). The dendritic cells, however, are unaffected by the mutation. They are present in *op/op* mice in all tissues in which they are normally found and in normal frequency (Takahashi et al., 1993).

In view of the above, Naito et al. (1991) and Takahashi et al. (1993) proposed that dendritic cells differentiate through a pathway distinct from that of the majority of macrophages (there is a subpopulation of macrophages that do not require CSF-1 for their differentiation), and that they must originate either from GM-CFCs directly or from some earlier hemopoietic precursor cells.

MONOCYTES AS PRECURSORS OF MICROGLIA

Microglia are considered to belong to the mononuclear phagocyte system because they express Fc and CR3 receptors, are capable of immune phagocytosis and may contain lysozyme, nonspecific esterase, and peroxidase in their cytoplasm, all basic requirements for inclusion of a mononuclear phagocytic cell in the mononuclear phagocyte system. Membership in the system implies that cells have common cell markers and/or functions similar to those of other members of the system and that they all have a common origin. It also implies cell origin from hemopoietic stem cells along the monoblast-monocyte lineage. The suggestion that microglia may have an origin other than from the hemopoietic stem cells, challenges one of the basic premises of the mononuclear phagocyte system.

The notion that microglia form from monocytes was proposed originally by Sántha and Juba (1933) and expanded on by Juba (1934). Since then the literature on the subject has become voluminous. Considerable confusion exists as to what constitutes a lineage; a practical definition of a cell lineage was given recently by Herzenberg and Kantor (1993) as "the set of cells deriving from distinct, relatively undifferentiated (unrearranged) progenitors that have at least a limited capacity for self-renewal and give rise to progeny that are committed to differentiate into cells distinguishable by particular functional or phenotypic characteristics." To define a cell lineage, its hierarchical arrangements, kinetics, and regulation of cell progression along the lineage at the molecular level must be demonstrated. In studying the lineage of monoblasts-monocytes-microglia the difficulty is to recognize various blood leukocytes that have infiltrated the CNS (Sedgwick et al., 1991). The first attempts to prove that microglia are, indeed, of monoblast-monocyte lineage used carbonated silver impregnation, vital dyes, colloidal carbon particles, incorporation of [^{3}H]TdR into the DNA as cell markers and morphological studies, light and electron microscopy. Although all this work was conceptually sound and seemed to support the hypothesis, it did not give direct proof that monocytes do indeed transform into microglia (Matsumoto and Ikuta, 1985; Matsumoto et al., 1985; Schelper and Adrian, 1986; De Groot et al., 1992; Lassmann et al., 1993).

Then followed the use of more sophisticated methods to identify cells by means of antibodies such as F4/80 (unknown antigen), Mac-1 or OX42 (CR3 receptor), antivault antibodies (large-size ribonuclear-protein particles) (Chugani et al., 1991), and ED-1 antibodies (macrophage functional-state antigen) and lectins, particularly *Griffonia simplicifolia* isolectin-B_4 (GSA I-B_4). The problem in using presently available antibodies is that the immunoreactivity expressed on microglia is shared with the same im-

munoreactivity on monocytes and macrophages. The exceptions are the lectins, which seem to have more specificity to ameboid and ramified microglia (Streit, 1990; Boya et al., 1991). Recently, a number of new antibodies have been developed, but they have not yet been sufficiently investigated (Esiri and McGee, 1986; Gehrmann and Kreutzberg, 1991; Flaris et al., 1993).

In spite of these difficulties, studies using antibodies and lectins pinpointed the timing and location of the appearance of monocytes-macrophages-microglia in the CNS in embryos, fetuses, and adult animals. The exact interphase between monocytes and microglia, however, still remains elusive and subject to the individual investigator's interpretation. Based on these studies, it is generally agreed that ramified cells in the parenchyma throughout the CNS are the "resting" form of microglia. It is also generally agreed that F4/80-positive cells found in the blood vessels and connective tissue of the leptomeninges, choroid plexus, and in Robin-Virchow spaces around the blood vessels in the CNS parenchyma are either monocytes or macrophages.

The vascularization of the CNS begins from the prominent perineural vascular plexus that surrounds the CNS. Vascularization has a caudal-cephalic gradient and commences at the myelencephalon and progressively ascends through metencephalon, mesencephalon, diencephalon, and telencephalon (Marin-Padilla, 1985). The capillary sprouts perforate the CNS and the penetration of the leading endothelial cells is achieved by focal degeneration and disintegration of subadjacent glial endfeet. Fragments of degenerating membranes and disintegrating processes are always found around the perforating endothelial cells (Marin-Padilla, 1985, 1988). The disintegrating cells attract monocytes and macrophages from the blood circulation.

No F4/80 positive cells have been found in the CNS before blood vessels begin to invade (Hume et al., 1983), although in the retina of rabbits nucleoside diphosphatase (NDPase) positive microglia appear at least 1 week before the onset of vascularization of the retina (Schnitzer, 1988, 1989). In mice, vascularization occurs between embryonic days 10 and 15, and at corresponding times in other animals (Strong, 1964; Bär and Wolff, 1972; Marin-Padilla, 1985, 1988). At embryonic day 10, F4/80 positive cells are seen in the leptomeninges (Andersen and Matthiessen, 1966; Morris et al., 1991; S. Fedoroff, I. Ahmed and G. Blevins, unpublished observations). During capillary invasion, single F4/80 positive cells are found in the CNS in the vicinity of capillaries. They are usually round or irregular in shape and may have some pseudopodia. The cytoplasm often appears vacuolated. The morphology of the F4/80 cells in the CNS is very similar to other F4/80 positive cells in the leptomeninges. The overall impression is that the F4/80 positive cells probably migrate into the CNS because of attraction by dead neural cells (Perry et al., 1985; Gordon et al., 1992; Ling and Wong, 1993).

Esiri et al. (1991) analyzed sections of necropsy brain tissue from fetuses and infants ranging in age from 18 weeks gestation to 8 months postterm. He found that fetuses of less than 28 weeks of gestation had a great concentration of macrophages in the ventricular zone (germinal matrix). They also saw macrophages in perivascular sites, leptomeninges, and subependymal regions. They observed fully developed microglia at 35 weeks of gestation. Hutchins et al. (1990) also observed great accumulations of ameboid cells with short processes in the ventricular zone (germinal matrix) of human fetuses at 13 to 24 weeks of gestation. They identified microglia positive for *Ricinus communis* agglutin-1 (RCA1) as early as 13 weeks of gestation.

At about embryonic days 15 to 16 in rats there is a greater influx of F4/80$^+$ cells into the CNS, and around birth, ameboid hemopoietic cells appear in large numbers in the corpus callosum (Imamoto and Leblond, 1978; Ling et al., 1980). The round, ameboid hemopoietic cells and Mac-1 positive cells gradually disappear during postnatal development (Imamoto and Leblond, 1978; Matsumoto and Ikuta, 1985; Ling and Wong, 1993).

In late embryonic development (embryonic days 18 to 19) in rats, some ramified F4/80$^+$ cells begin to appear in the parenchyma. They have an entirely different morphology than that of the F4/80$^+$ cells seen in earlier embryos (Perry et al., 1985). These cells have little cytoplasm but have several long processes that branch several times. The processes seem to be covered with very fine protrusions (Perry et al., 1985). It is generally agreed that these are ramified microglia. Their numbers gradually increase, then increase dramatically between postnatal days 5 and 15. By day 15 the entire parenchyma is filled with these ramified microglia, each one occupying its own territory with no overlapping. In different areas of the CNS, the density of the cells varies from 5 to 20% of cells (Kreutzberg, 1987; Lawson et al., 1990). There is no correlation, however, between the density of the ramified microglia and areas where there had been high cell death. The two phenomena appear to be independent (Lawson et al., 1990).

From these studies it becomes clear that hemopoietic macrophages are present and play a significant role in the developing nervous system. This is not surprising, since many dying cells and cell debris

have to be removed, hence the attraction of macrophages to the developing nervous system. However, as the system develops, the number of dying cells decreases and so does the number of hemopoietic macrophages, although some are always present in the CNS.

The development of microglia seems to be an independent process; they appear much later in development, have a specific developmental "window" when they proliferate, and eventually occupy the whole parenchyma of the CNS and, functionally, become closely integrated with the neurons and astroglia and probably also with the oligodendroglia (Fedoroff, 1990; Fedoroff et al., 1993).

A number of investigators who have extensively studied the invasion of macrophages into the CNS and the development of microglia conclude that no intermediate forms are present (Choi, 1981; Matsumoto and Ikuta, 1985; Matsumoto et al., 1985; Shelper and Adrian, 1986; De Groot et al., 1992). However, others do describe transitional forms (Imamoto and Leblond, 1978; Ling et al., 1980; Perry et al., 1985; Ling and Wong, 1993). Considering the great plasticity of microglia and how easily they acquire different phenotypic expressions, it may be very difficult to determine on morphological grounds whether a given morphological phenotype is due to cell modulation or to differentiation into a more advanced cell form.

TURNOVER OF MICROGLIA IN CENTRAL NERVOUS SYSTEM PARENCHYMA

The turnover rate of microglia has been studied using [^{3}H]TdR or [^{14}C]TdR incorporation and using bone marrow chimeras with genetic markers. Korr (1980) identified microglia using silver carbonate impregnation followed by autoradiography. When he injected mice with [^{14}C]TdR between postnatal days 10 and 14, he found that in 45-day-old mice about 50% of microglia were labeled. When the mice were injected between days 15 and 19, only 5% of microglia were labeled in 45-day-old animals. However, if the injections were made after day 20, no labeled microglia were found. Similar observations were made by Imamoto and Leblond (1978). When they injected [^{3}H]TdR into postnatal day 5 rats they found 78.1% labeled microglia in day 12 animals and 91% in day 19 animals. However, rats injected with [^{3}H]TdR on day 19 or day 20 had a significantly smaller number of labeled microglia (Imamoto et al., 1978) and when the injections were made after day 25, there were no labeled microglia.

The turnover of microglia in adult animals was studied by McCarthy and Leblond (1988) who identified microglia in semithin sections stained with toluidine blue. They infused [^{3}H]TdR into adult mice for 7 days and observed only one labeled pair of microglia. After 30 days of infusion only two labeled microglia were seen. They therefore concluded that in adult animals microglia normally do not divide (McCarthy and Leblond, 1988). Lawson et al. (1992), however, using F4/80 antibody to identify microglia, injected 3-month-old mice with methyl-1',2'[^{3}H]TdR and found that after 1 hour 0.05 to 0.06% of microglia were labeled; after 24 hours, 0.14 to 0.24%; and after 48 hours, 0.23 to 0.24%. They concluded that in adult animals microglia have a slow turnover rate.

From these observations it can be concluded that microglia develop primarily after birth and mainly between postnatal days 5 to 20, the time when microglia are proliferating rapidly, corresponding to actual observations of a tremendous increase in the number of microglia present in the parenchyma all through the CNS (Perry et al., 1985; Lawson et al., 1990; S. Fedoroff, unpublished results).

There is a discrepancy in findings pertaining to turnover of microglia in adult animals, probably due to different sampling methods used. Lawson et al. (1992) found a very slow turnover using immunocytochemistry. Others (Imamoto and Leblond, 1978; Korr, 1980; McCarthy and Leblond, 1988), using morphological methods, however, concluded that microglia do not divide in adult animals. It is possible that microglia are long-living, nondividing cells during steady-state conditions. It is also possible that microglia have a very long cell cycle; they have not lost the ability to divide, because in case of brain or spinal cord injury, they can suddenly proliferate. They also proliferate extensively in tissue culture in the presence of CSF-1.

The conclusions obtained with incorporation of [^{3}H]TdR are colored by the limitation of [^{3}H]TdR technology, which can reliably measure only cells that have short cell cycle times; cells with long cycle times are not detected by a [^{3}H]TdR assay. [^{3}H]TdR incorporation into the cell's DNA is possible only during the S phase of the cell cycle, when new DNA is synthesized. The S phase is generally relatively short, 6 to 12 hours. However, the G_1 phase of the cycle is variable, and if microglia have an exceptionally long G_1 phase, chances to incorporate [^{3}H]TdR during the S phase are meager. New technology utilizes protein specific to G_1 and G_0 phases of the cell cycle. Cyclins are found in the G_1 phase of the cell cycle of dividing cells (Waseem and Lane, 1990; Foley et al., 1991; Berlingin et al., 1992; Sasaki et al., 1992) and statin in the G_0 phase of nondividing cells

(Fedoroff et al., 1990; Shipper et al., 1992, 1993). Using antibodies to cyclins and statin it will be easier to determine whether microglia are in a cell cycle with a very long G_1 phase, or are differentiated cells in the G_0 phase.

Another approach to determination of cell turnover was to use radiation bone marrow chimeras. In these studies polymorphism of MHC class I antigens was used as a marker. Lewis rats express MHC class I type RT-1^l and DA rats express MHC class I type RT-1^a molecules. The bone marrow of the F_1 hybrids of these rats expresses MHC class I type RT-$1^{a/l}$. The bone marrow of such F_1 hybrid rats was injected into irradiated (1000 R) DA rats and the donor bone marrow progeny were identified with Il-69 monoclonal antibody, which immunoreacts with RT-1^l haplotype of the MHC class I molecule. The other type of bone marrow chimera was constructed by using F_1 hybrids of Lewis rats (MHC class I type RT-1^l) and PVG rats (MHC class I type RT-1^c) as bone marrow donors. The bone marrow of F_1 animals was injected into irradiated (900 R) Lewis rats. The OX27 monoclonal antibody recognizes c haplotype of MHC class I molecules. If microglia originate from the monoblast-monocyte lineage in the bone marrow, it would be expected that after a certain period of time the host's microglia would be replaced by new chimeric donor bone marrow cells carrying their specific MHC class I type haplotype. The chimeric CNS was analyzed with antibodies specific to donor type I MHC haplotype, 2 months up to more than 1 year after the reconstitution of the animals with marked donor bone marrow (Matsumoto and Fujiwara, 1987; Hickey and Kimura, 1988; Sedgwick et al., 1991; Hickey et al., 1992).

The results of all these studies with chimeric animals are mutually supportive, and there is general agreement that monocytes-macrophages in leptomeninges, choroid plexus and perivascular areas are indeed replaced by cells from the bone marrow. Within the leptomeninges, 60 to 70% of monocytes-macrophages are replaced by donor bone marrow cells, in choroid plexus, 20%, and in the perivascular area, 20 to 40%, during the 2 months after replacement of bone marrow.

In the CNS parenchyma, 5 to 10% of cells had donor bone marrow cells with MHC class I type markers. These were small round cells with prominent nuclei, a thin rim of cytoplasm and short processes. The cells were located either free in the Virchow-Robin space or situated along capillaries or small vessels between the basement membrane of the endothelial cells and the astroglial foot processes of the glia limitans (Hickey and Kimura, 1988; Graeber et al., 1989; Lassmann et al., 1991; Hickey et al., 1992). These cells were identified as lymphocytes. Only a very few parenchymal ramified microglialike cells expressed donor MHC class I haplotype (Matsumoto and Fujiwara, 1987; Hickey et al., 1992). Bone marrow chimeras that remained chimeric for periods beyond 1 year past marrow transfer still exhibited only scattered, rare, ramified microglialike cells expressing donor bone marrow MHC class I haplotype (Sedgwick et al., 1991; Hickey et al., 1992).

To stimulate turnover of bone marrow-derived cells in the CNS, Lassmann et al. (1993) developed experimental allergic encephalomyelitis (EAE) in rats with radiation bone marrow chimeras by injecting intravenously myelin basic protein reactive T-lymphoblasts. They analyzed the CNS of these rats at the peak of the disease and 3 months after recovery from inflammation. In recovered animals, 90% of the cells in the meninges had donor bone marrow MHC class I haplotype; 4.4% in the perivascular space; and 5.6% in the parenchyma of the CNS. Most donor bone marrow MHC class I haplotype positive cells in the parenchyma were small and round, without processes. They were positive for antigens characteristic to T lymphocytes. Only 0.6% of all donor bone marrow MHC class I haplotype positive cells had morphology characteristic to ramified microglia. They concluded that the ramified microglia, resident in the parenchyma of the CNS, are extremely sessile, even in pathological conditions, and are not replaced by bone marrow-derived marked cells in any significant numbers (Lassmann et al., 1993).

Sedgwick et al. (1991) induced inflammation in the CNS of bone marrow chimeric rats either by intracellular inoculation with the neurotrophic murine hepatitis virus strain JHM or by subcutaneous injection of myelin basic protein. After 7 days, the rats were killed and the microglia and hemopoietic cells present in the CNS were isolated by first disaggregating the cells by passing through a stainless steel sieve, and then by collagenase. The cells were then separated on a Percoll gradient and immunoreacted with a number of antibodies. The immunoreacted cell populations were analyzed by cytofluorographic analysis using an FACScan. With this procedure the microglia could be distinguished from the infiltrating lymphocytes, primarily by the degree of expression of CD45 panhemopoietic cell antigen. In such preparations microglia expressed the host's MHC class I haplotype molecules but not the donor type (Sedgwick et al., 1991). Even after one year of the chimeric state the microglia did not change (J.D. Sedgwick, personal communication).

In all the above experiments polymorphism of

MHC class I molecules was exploited to identify cells. The problem is that not all cells express MHC class I molecules to the same degree (Wong et al., 1984; Perry and Gordon, 1988); therefore, before analysis the animals had to be injected with murine gamma-interferon (INFγ) and murine tumor necrosis factor-alpha (TNFα) to upregulate the expression of MHC class I antigen. There is some probability that not all cells respond to upregulating of the MHC class I molecules to the same degree.

De Groot et al. (1992), therefore, used bacteriophage λ transgenic mice as bone marrow donors. Bacteriophage λ is incorporated into the genome of the transgenic animals and therefore, in contrast to the protein markers, it is a very stable marker and is not subject to the posttranslational or posttranscriptional modification. They transplanted the bone marrow (from transgenic mice) into recipient 1-day-old or adult (3-month-old) mice. Integrated copies of λ DNA donor cells were detected by *in situ* hybridization, and the types of cells were identified by prior immunocytochemistry. They found, as others had, many donor bone marrow-derived cells in the leptomeninges, ventricles, and occasionally in blood vessel walls in the brain parenchyma. These cells resembled macrophages; they had round or ovoid nuclei and extensive cytoplasm and were devoid of processes. They also found approximately 10% of microglialike cells that displayed the donor transgenic signal in the white matter of the cerebellum, medulla oblongata, and corpus callosum. No microglialike cells having the donor transgenic signal were found in the gray matter. De Groot et al. (1992) concluded that microglia constitute a heterogeneous cell population and that only a small portion are derived from newly recruited bone marrow precursors, whereas the majority of the microglial cells must have come from locally present precursors, presumably of neuroectodermal origin.

From the experiments using isotope incorporation into DNA and those using chimeric animals, it can be concluded either that microglia are long-living cells with an extremely low turnover rate or that their origin and turnover rate during adult life does not depend on infiltration of cells from the bone marrow. Another possibility is that the CNS is colonized by some of the hemopoietic stem cells during the early stages of embryonic development and that the stem cells become resident cells of the CNS, responsible for formation and regular turnover of microglia during adult steady-state conditions, and having the ability to respond in pathological conditions where increased numbers of microglia are required (Sedgwick et al., 1991). If such hemopoietic stem cells are indeed present in the CNS, they must retain their ability to self-replicate to maintain a constant microglia cell population under steady-state conditions. At the same time, the neural microenvironment must have restricted these stem cells from forming other hemopoietic cells, as such cells are not seen in the CNS. In addition, the phenotype of monoblast-monocyte precursor cells would have to be modified from that in the bone marrow, because in adult brain, monoblasts-monocytes, which in this possibility would be the precursors of microglia, are not seen in the parenchyma to the extent they should be if they are indeed the precursors of microglia during development and adult life.

For purposes of an overview, it is important to mention that in all the above studies many small hemopoietic cells were found in the CNS parenchyma and were identified as lymphocytes (Lassman et al., 1991; Sedgwick et al., 1991; De Groot et al., 1992). It has been proposed that the CNS is continuously patrolled by a small number of T lymphocytes and monocytes-macrophages. However, they do not remain in the CNS for a long time, probably 1 or 2 days (Hickey et al., 1991), although there is evidence that some T lymphocytes can survive in the CNS for several months (Sedgwick et al., 1991). In the presence of antigens the "patrolling" T lymphocytes and macrophages can remain in the CNS, or cyclically reenter to initiate inflammation (Ferrer et al., 1990; Hickey et al., 1991).

HEMOPOIETIC STEM CELLS IN THE CENTRAL NERVOUS SYSTEM

Techniques to detect and measure the number of hemopoietic stem cells within hemopoietic tissue are well established. To detect self-replicating multipotential stem cells, mice are irradiated (1000 R) and dilutions of hemopoietic cells are injected into the mouse's tail vein. The multipotential stem cells present in the injected sample home in the spleen and form clones. By analyzing the composition of the clones, the type of stem cell that gave rise to them can be identified and by counting the number of clones (colonies) found in the spleen, the number of stem cells present in the injected sample can be calculated (Metcalf, 1984).

If, during embryogenesis, the CNS is colonized by hemopoietic stem cells, then they should be detectable by a spleen colony assay. Bartlett (1982) disaggregated whole brains from (CBA X BALB)F_1 mice and injected cells into irradiated (850 R) CBA mice. After 9 days, he examined the spleens and found 14 spleen cell colonies per 10^5 cells injected into adult animals, and 8.9 spleen cell colonies per

10^5 injected cells in 3-day-old animals. He also used disaggregated cell suspensions from the brains of W^f/W^f mice to successfully cure congenital anemia in W^f/W^f mice when transplanted cells from bone marrow of W^s/W^s mice were unable to do so. He concluded that mouse brain does, indeed, have pluripotential hemopoietic stem cells that probably colonize the CNS during early embryogenesis and that in the appropriate environment (spleen) they are capable of giving rise to various hemopoietic cells.

Hoogerbrugge et al. (1985) was unable to obtain the same results when he repeated Bartlett's experiments. They could not find hemopoietic stem cells in the brains of W/W^v mice and injection of disaggregated brain cells into three different strains of mice yielded only 2.6 to 5.7 spleen cell colonies per brain. However, when the brains were carefully washed in balanced Hanks' solution following dissection, the number of spleen colonies in the irradiated host animals decreased to 0.1 to 0.4 colonies per brain. They could also recover hemopoietic stem cells from the wash fluid. They concluded that most of the cells in Bartlett's preparations must have been derived from contaminating bone marrow and blood (Hoogerbrugge et al., 1985).

In collaboration with Dr. A.A. Axelrad, University of Toronto, we obtained results similar to those of Hoogerbrugge et al. (1985). We used newborn C_3H/HeJ mice as a source of neopallial cells and injected the cells into irradiated (925 R) 10-week-old (C_3Hf/Bi X C_{57} B1/6)F_1 hybrid mice. We obtained 2.3 spleen colonies per 10^6 injected cells. We also injected cells from tissue cultures initiated from newborn C_3H/HeJ mouse neopallia, which formed microglialike cells. (For more detail, see below). The injection of 10^6 cultured neopallial cells yielded on the average 1.7 spleen colonies. When we analyzed the colonies formed by injecting neopallial cells and tissue culture cells, all cells had the Y chromosome corresponding to the male sex chromosome of the recipient mice and one "marker" chromosome of the recipient mice, indicating that the spleen colonies were of host radiation residual stem cell origin and not from transplanted cells (Hao et al., 1991).

In addition, we grew cells of neopallial cell tissue cultures in methylcellulose cultures which are used to detect granulocyte-macrophage colony-forming cells (Guilbert and Iscove, 1976; Iscove et al., 1982; Metcalf, 1984). After 16 days of incubation with and without monocyte-macrophage growth factors (IL-3 and CSF-1), no proliferation of cells could be detected, indicating that no monocyte-macrophage precursor cells were present in cultures.

From the experiments of Hoogerbrugge et al. (1985) and our experiments (Hao et al., 1991), we concluded that mouse brains do not contain hemopoietic stem or precursor cells that are detectable by the classical spleen colony assay (Till and McCulloch, 1961), or by methylcellulose cultures (Guilbert and Iscove, 1976; Iscove et al., 1982; Metcalf, 1984).

ORIGIN OF MICROGLIA IN TISSUE CULTURE

Hao et al. (1991) demonstrated that when neopallial cell cultures are subjected to nutritional deprivation (i.e., no medium change), microglia develop preferentially. The explanation was that during the period of nutritional deprivation when the culture medium is not changed, microglial trophic factors, including CSF-1, secreted by astroglia, accumulate in a concentration sufficient to stimulate microglial differentiation. Nutritional deprivation is therefore the method of choice to produce microglia in cultures and to study their differentiation (Hao et al., 1991; Richardson et al., 1993; Fedoroff et al., 1993; Neuhaus and Fedoroff, 1994). To engender fuller appreciation of these observations I will describe the culture system used.

The cultures are usually initiated from neopallia of newborn C_3H/HeJ (endotoxin resistant) mice. After 8 to 10 days in culture, a monolayer of cells forms. In dense cultures, better than 95% of the cells are GFAP-positive, indicating that they belong to the astroglia lineage. Usually less than 1% of the cells express macrophage-specific antigens such as Mac-1 or F4/80, and these cells can be eliminated from the culture by complement-mediated immune-cytotoxicity (Hao et al., 1991). When the medium is no longer changed, pleomorphic phase-dark cells appear on the surface of the layer of astroglia. The astroglia begin to retract from the plastic substratum, providing free space for the newly formed cells to attach to the plastic. When they adhere to the plastic surface they assume typical ameboid cell morphology and develop a number of vacuoles in their cytoplasm. These cells are highly motile. After 10 to 12 days of nutritional deprivation, the whole culture is populated with the ameboid microglia. At the same time, the astrocytes retract from the substratum and form clumps that can easily be washed out from the cultures. Thus, in conditions of nutritional deprivation, in a period of 8 to 10 days, the monolayer culture initiated from the neopallia of newborn mice completely transforms into a culture of microglia (Hao et al., 1991, 1992).

In cultures, microglia can assume several different morphological forms, for example, ameboid, ramified, rod-shaped, round-flat shape, and spindle shape

(Jordan and Thomas, 1988; Hao et al., 1990; Suzumura et al., 1991; Ward et al., 1991; Abd-El-Basset and Fedoroff, 1995). Microglia in neopallial cell cultures have typical macrophage ultrastructure. They can mediate Fc-immune phagocytosis and secrete lysozyme into the medium. They express vimentin, Mac-1, Mac-3, F4/80, Fc, CR3, LC-1, and MHC class II antigens, take up Dil-ac-LDL and contain nonspecific esterase. They differ from macrophages of bone marrow, spleen, and peritoneal exudate in that they do not attach firmly to the plastic substratum (Hao et al., 1991).

We were able to generate microglia in cultures initiated from every stage of mouse embryonic development, beginning with Theiler stage 13 (8.5 days of gestation). Thus the formation of microglia in culture is not related to any specific developmental stage (Hao et al., 1991). It follows that microglia precursor cells must be present throughout the developing CNS and in cultures these cells are neither morphologically nor immunologically distinguishable from astroglia precursor cells, that is, they are vimentin$^+$, GFAP$^-$, Mac-1$^-$, and F4/80$^-$. To determine the number of precursor cells present in a culture initiated from neopallia of newborn animals, we used a limiting dilution analysis and found that one in every 8 cells (12%) in cultures is a potential microglia precursor cell (Richardson et al., 1993). Twofold serial dilutions (up to 50 cells per culture well) of disaggregated neopallial cells, in the presence of trophic factors, generated in cultures at every dilution point approximately the same frequency of microglia or microglia-containing cell colonies, indicating that the microglia formation was independent of dilution of neopallial cells (number of neopallial cells planted per culture).

Using nutritionally deprived neopallial cell cultures we unexpectedly found that at the time the numbers of microglia were increasing rapidly in the cultures, no cell divisions could be detected. When we triple labeled the cultures for Mac-1, GFAP, and BrdU, no Mac-1$^+$/BrdU$^+$ cells could be found, indicating that no microglia progenitor cells divided. BrdU$^+$ cells (dividing cells) that were present were always either GFAP$^+$ or GFAP$^-$. Infecting the cultures with a retrovirus having a marker lacZ reporter gene did not produce microglia that had the marker (Neuhaus and Fedoroff, 1994).

It should be stated, however, that in cultures that receive microglial growth factors IL-3, IL-6, and CSF-1 at the time of regular medium change, microglia form equally well and proliferate. The massive cell death that occurs in cultures subjected to nutritional deprivation does not take place (Richardson et al., 1994). Therefore the extensive cell death is not a factor in microglia formation in cultures. They require appropriate growth factors and require these at certain concentrations and in certain combinations, in order to differentiate (Richardson et al., 1994).

This indicates that microglia progenitor cells in neopallial cell cultures that are subjected to nutritional deprivation are in a quiescent state and that in the presence of appropriate trophic factors, secreted by astroglia, they transform into Mac-1$^+$ microglia directly, without cell division. Once they have transformed, then in the presence of CSF-1 (macrophage growth factor) they proliferate and expand the population of Mac-1$^+$ microglia in the culture (Neuhaus and Fedoroff, 1994). Alliot et al. (1991) also described the presence of microglia progenitor cells in astroglia cultures. In their cultures the progenitor cells were Mac-1$^+$/F4/80$^-$ and on culturing they became Mac-1$^+$/F4/80$^+$. These progenitor cells proliferated vigorously when seeded on an astroglia feeder layer. It seems that the microglia progenitor cells described by Alliot et al. (1991) have progressed further along the lineage of cell differentiation than the ones we describe and that they could proliferate on top of astroglia because astroglia constitutively secrete macrophage growth factor CSF-1.

Where do the microglia precursor cells come from? I have mentioned that we were able to develop microglia in cultures initiated at any developmental stage. To find out whether neuroectoderm is the source of microglia precursor cells, we initiated cultures from neuroepithelium dissected carefully from C_3H/HeJ mouse embryos at Theiler stage 13 (day 8.5 of gestation). At this developmental stage the neuroepithelium of the neural tube is not vascularized and monocyte-macrophage cells have not yet begun to appear either in the yolk sac or elsewhere in the embryo. To minimize the possibility that some mesodermal cells might still be attached to the neuroepithelium, it was treated lightly with a trypsin solution to dislodge any mesodermal cells still attached. The neuroepithelium was cut into small fragments and grown in cultures for 20 days, with regular feeding every 2 to 3 days. After 20 days, the medium was not changed again, and after an additional 10 to 14 days in such nutritionally deprived culture conditions, many microglia appeared. These experiments strongly suggest that microglia can originate from neuroepithelium as do other glia.

It is possible that microglia develop from glioblasts and are closely related to the astroglia lineage, from which they may branch off around the time of birth, when high rates of microglia proliferation have been observed (Imamoto and Leblond, 1978;

Korr, 1980) or, possibly, branch off earlier in development but remain quiescent until birth. Microglia and astroglia are closely related functionally (Fedoroff et al., 1993). Astroglia secrete CSF-1, the growth factor for microglia which require it for survival, proliferation, and differentiation (Fedoroff et al., 1993). However, microglia seem to be very plastic and CSF-1 does not seem to be always essential for their differentiation.

Mice homozygous for the *op* mutation, as mentioned before, have severe osteopetrosis, because of their lack of osteoclasts (which form from macrophages). The recessive osteopetrotic *op* mutation in mice results in a total lack of CSF-1 in body fluids and tissues (Wictor-Jedrzejczak et al., 1990; Yoshida et al., 1990), but production of the other cytokines, GM-CSF and IL-3, which are involved in mononuclear phagocyte cell differentiation, is unaffected or even increased (Wictor-Jedrzejczak et al., 1990). Mononuclear phagocytes in *op/op* mice are depleted to varying extents in different tissues (Naito et al., 1991; Wictor-Jedrzejczak et al., 1992; Witmer-Pack et al., 1993). However, Naito et al. (1991), Takahashi et al. (1993), Witmer-Pack et al. (1993), and Blevins and Fedoroff (1995) reported that microglia are not depleted in the brains of *op/op* mice. The frequency and morphology of microglia in *op/op* mice in various parts of the brain are similar to those in their littermates (+/?) or mice of other strains that normally produce CSF-1 (Blevins and Fedoroff, 1995).

In our experiments the neopallial cells from newborn *op/op* mice in cultures without medium change did not form microglia and the astroglia did not secrete CSF-1; whereas the neopallial cells from their +/? littermates in cultures grown without medium change did form microglia and the astroglia did secrete CSF-1 into the medium. When we added CSF-1 to the cultures of neopallial cells from newborn *op/op* mice, Mac-1 positive microglia formed (Blevins and Fedoroff, 1995). This indicated that microglia precursor cells are present in the newborn *op/op* mice, and that they require CSF-1 for development in cultures. *In situ,* however, in *op/op* mice microglia can form in the absence of CSF-1. It is likely that factor(s) which substitute for CSF-1 *in situ* in *op/op* mice are produced locally (Blevins and Fedoroff, 1993).

There are certain similarities between microglia in the CNS and Langerhans cells in the epidermis. Both are antigen-presenting, both express CR3, Fc, and Ia receptors (Fossum, 1989; Perry and Gordon, 1991) and their numbers are not affected in *op/op* mice (which are deficient in CSF-1). The difference between the two cell types is that Langerhans cells in cultures depend for viability and function on GM-CSF, but microglia depend on CSF-1 (Witmer-Pack et al., 1987; Heufler et al., 1988; Fedoroff et al., 1993, Blevins and Fedoroff, 1995). The numbers of Langerhans cells in the epidermis of *op/op* mice and the numbers of microglia in the CNS of such animals are unaffected by the mutation, but for different reasons. Langerhans cells develop normally because in *op/op* mice the production of GM-CSF is unimpaired. Microglia, however, develop normally in spite of the total absence of CSF-1, probably by utilizing an alternate pathway of differentiation that does not include CSF-1.

The observations made on tissue cultures indicate that microglia can be produced by neuroepithelial cells and that the neopallia of newborn animals have cells that are Mac-1 negative which under appropriate culture conditions can form microglia. The studies of osteopetrotic mutant *op/op* mice indicate that microglia differ from dendritic cells and that both microglia and dendritic cells differ from classical macrophages.

ORIGIN OF MICROGLIA *IN SITU*

Recently McKanna (1992, 1993a, 1993b), using immunocytochemistry, showed that in rats microglia and their progenitor cells are immunoreactive for lipocortin-1 (LC-1). By using this "marker" he could pinpoint the glia raphe of the floor plate of the hindbrain and spinal cord as the site of origin of microglia. Because of the significance of this observation, I will expand on the development of the floor plate of the neural tube.

During the gastrulation stage of development the bilaminar embryonic disc is converted into a trilaminar disc. This stage is marked by the epiblastic cells (from which all three germ layers develop) beginning to converge in the midline of the dorsal aspect of the embryonic disc. They form a linear band, the primitive streak, which invaginates. The cells in the primitive streak lose their attachment to the epiblastic cells and migrate laterally between the epiblast (future ectoderm) and hypoblast (future entoderm), thus forming a loose network of mesoblast, which forms the intraembryonic mesoderm.

At the cranial end of the primitive streak, cells accumulate and form the primitive knot and a pit from whose rostral lip the cells segregate. Some form the notochord which grows in the midline between ectoderm (former epiblast) and entoderm (former hypoblast). However, cell marking experiments have shown that other cells of the rostral lip of the primitive pit migrate rostrally in the midline above the

notochord and form the floor plate (notoplate) of the neural tube (Jacobson and Gordon, 1976).

Whether or not the cells in the primitive knot are already determined as becoming neuroepithelial cells that form the floor plate (notoplate) or becoming cells that form the notochord, is not known. In amphibians they are segregated, but both form from the same blastomere (Jessell et al., 1989). Thus there is a view that cells of the notochord and the cells of the floor plate (notoplate) of the neural tube have a common ancestry. This view, however, has not yet been generally accepted (Jessell et al., 1989; McKanna, 1993b).

The cells of the floor plate differentiate early in embryogenesis to form a glial raphe as the lateral parts of the neural plate begin to fold into a neural tube (Jessell et al., 1989; McKanna, 1993b). The cells of the raphe are primitive glial ependymal (PGE) cells which form the midline axis. This axis subdivides the ventral part of the pons and spinal cord into two symmetrical compartments. The raphe spans through the hindbrain and spinal cord.

In transverse sections of E16.5 rat embryos, the LC-1 raphe forms in the median one third of the floor plate. It consists of pseudostratified epithelial cells, the primitive (archetypic) glial ependymal (PGE) cells, which span the whole thickness from the fourth ventricle in the pons, or the central canal in the spinal cord, to the pia, a distance in the pons of approximately 500 μm and in the spinal cord, 150 μm. The width of the LC-1 raphe in paraffin sections is approximately 20 to 30 μm, and it consists of 5 to 8 PGE cells with their nucleus in the apex and their long thin process distal toward the pia.

It is these PGE cells that stain positively with LC-1. The first staining appears in the rhombencephelon at E11 and reaches the lumbar cord by the end of E12. Staining of the raphe is maximal from E15 to E18 and subsequently declines (McKanna and Cohen, 1989; McKanna, 1993b).

LC-1 is a 35 kD Ca^{2+}-phospholipid binding protein that serves as a substrate for the EGF receptor tyrosine kinase (Fava and Cohen, 1984; McKanna, 1993b). It is also known as p35 or annexin I. LP-1 is a soluble intracellular protein, but it is also secreted by the cells. Extracellularly, it has an anti-inflammatory effect (Goulding and Guyre, 1992).

At the end of the first postnatal week, small LC-1-positive cells appear laterally from the LC-1-positive streak in the glial raphe. Their numbers increase and the most distally located LC-1-positive cells are ramified. By the fourth postnatal week a large number of LC-1-positive cells accumulate in the vicinity of the raphe and the raphe itself begins to decline. Some of the LC-1-positive cells have ameboid and some ramified morphology. By the sixth postnatal week and through adulthood, the LC-1-positive cells are present throughout the CNS in both the white and gray matter (McKanna, 1993b). The LC-1 positive cells are negative for S-100β, the marker specific for astroglia, but stain positively with HRP-labeled *Griffonia simplicifolia* isolectin-B_4(GSA I-B_4) which is used to demonstrate microglia (McKanna, 1993a, 1993b). The LC-1-positive ramified cells react to stab wounds or cortical ablation by increasing in number, acquiring ameboid morphology and becoming phagocytic (McKanna, 1993a).

In the previous section the formation of a highly enriched population of microglia in cultures was described. These microglia also immunoreact positively for LC-1 (Fedoroff and McKanna, 1994). Thus it seems likely that the LC-1-positive dendritic cells described by McKanna (1992; 1993a, 1993b) are indeed microglia and that they form from the PGE cells in the raphe of the floor plate of the hindbrain and spinal cord.

It is also significant, in this connection, that in the floor plate on either side of the LC-1-positive raphe, there are paramedian bands of cells that immunoreact with S-100β (McKanna, 1993b). McKanna followed these S-100β-positive cells and observed their lateral movement as development proceeded and that later they populated the CNS. The S-100β-positive cells in the CNS eventually had an astroglial morphology and immunoreacted positively for GFAP. Thus, both microglia and at least some astroglia form from PGE cells in the raphe of the floor plate of the neural tube (Figure 10-1).

CONCLUSIONS

Hemopoietic monocytes-macrophages are present in the CNS during most of development and their presence is related to neural cell death. They occur in large numbers throughout embryonic development, then decrease and finally are limited to a few cells that "patrol" the CNS. Mature microglia, on the other hand, are not present during the early stages of embryonic development. In mice and rats, they form in large numbers during the post-natal period and occupy the parenchyma throughout the CNS. Their density and distribution in the parenchyma of the CNS is not related to sites of neural cell death during embryonic development. Their numbers are constant in the steady-state condition during adult life. Microglia are part of the neuronal-glial network and thus are functionally closely integrated with other neural cells.

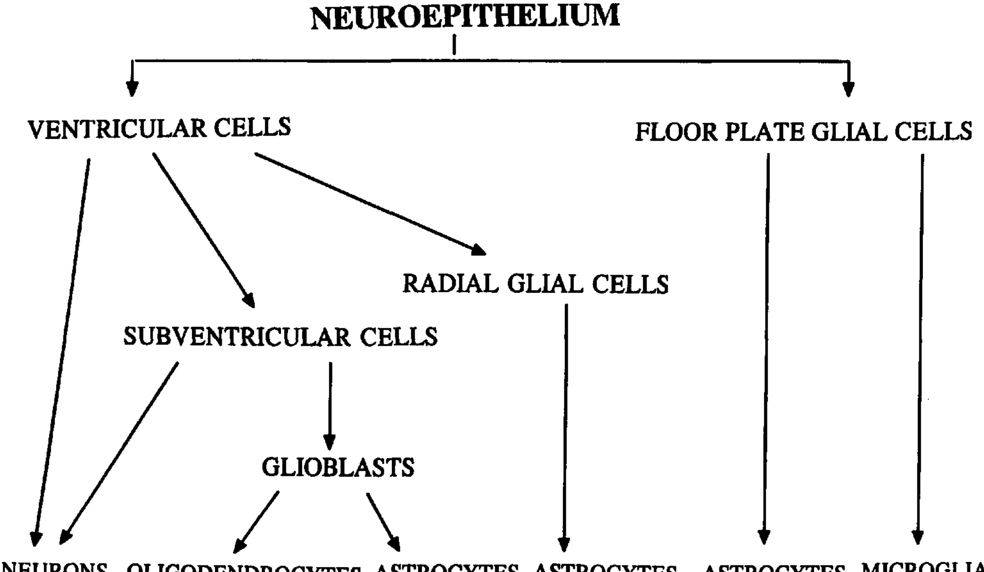

FIG. 10-1. Hypothetical scheme of gliogenesis. The proposal for glial development via ventricular and subventricular cells and glioblasts, and neuron development from ventricular and subventricular cells, was originally proposed by the Boulder committee (1970) (reviewed by Fedoroff, 1986; Levison and Goldman, 1993). Development of astrocytes from radial glia had already been proposed by Ramón y Cajal (reviewed by Schmechel and Rakic, 1979; Cameron and Rakic, 1991; Misson et al., 1991; Yang et al., 1993; see also Chapter 8, this volume). There is some evidence supporting the notion that oligodendroglia also develop in some parts of the CNS from radial glial cells (e.g., Hirano and Goldman, 1988). The development of the floor plate of the neural tube and the origin of microglia and astroglia from the glial raphe of the floor plate is described in the text. Oligodendrocytes may also originate in the ventral part of the spinal cord, but it is not clear whether they develop only from radial glia or also from primitive glial ependymal cells (Noll and Miller, 1993). It is also possible that some microglia develop via ventricular and subventricular cells and glioblasts, although the available data is not adequate (see text). A number of lineage choices appear to be available for glia in different regions of the CNS. Immature glia are motile and populate the CNS from the sites of their origin (see text). It is not known whether various glia cells for example, astroglia, that develop along different pathways, are identical or retain characteristics related to their lineage.

Attempts to demonstrate that microglia can be replaced in chimeric animals by marked monocytes-macrophages have been unsuccessful. In some cases a small number of microglialike cells had hemopoietic cell markers, but, considering the tremendous morphological plasticity of macrophages, it is not surprising that some could assume a morphology resembling that of microglia. Although microglia and macrophages share some common antigens and even functions, such as phagocytosis, this does not imply common origin. Searches for hemopoietic stem cells in the CNS have been unsuccessful. The recent findings that microglia originate from LC-1-positive primitive glial ependymal cells in the raphe of the floor plate of the hindbrain and spinal cord and that neuroepithelium taken from embryos at stages of development before vascularization of the CNS has occurred could generate microglia in cultures, strongly support the notion that microglia are of neuroectodermal origin as are all other glia (Figure 10-1), and that microglia are an integral part of the CNS fabric.

It is significant that microglia as well as at least some astroglia form from the primitive glial ependymal cells of the floor plate of the neural tube. Microglia and astroglia are closely linked functionally and microglia depend on CSF-1 secretion from astroglia. That they may also be closely linked developmentally does not seem impossible. Microglia express many phenotypic markers that are also expressed by hemopoietic mononuclear cells. Perhaps this is due to a common ancestry in developmental stages, even preceding development of the neuroectoderm and mesoderm.

On the whole, it seems unlikely that microglia form from hemopoietic cells. For over 70 years, research has been directed mainly to confirm the early claims that microglia do originate from pial or hemopoietic cells. Perhaps it is time to redirect the emphasis of the research and to concentrate on microglia as derivatives of neuroepithelium as are the other glia.

11 Potassium channels

STEVEN DUFFY, DOUGLAS D. FRASER, AND BRIAN A. MACVICAR

The analysis of the electrophysiological properties of glial cells is inspired by a desire to discover the functional roles of these cells in the intact nervous system. The output of neurons is easily documented and conceptualized (i.e., increased firing of action potentials or secretion of neurotransmitters) but except for myelination the roles for glia in the nervous system have still not been rigorously described. The close spatial relationship between glial cells and neurons suggests that glia may be important modulators of neuronal function. The proximity of glial endfeet to capillaries suggests that they may mediate the flow of nutrients to neurons. Although there is no obvious electrophysiological output from these cells, there is mounting evidence for the secretion of important factors such as growth factors or eicosanoids from glia. In our present conceptual framework for glia it is difficult to ascertain a functional role for voltage-gated ion channels. However, there is no doubt that glia express a diversity of ion channels approaching that of neurons. Elsewhere in this book inward Na^+ and Ca^{2+} channels and ligand-gated channels are discussed. Here we focus on the K^+ currents, which are the most predominant electrophysiological characteristics of glial cells.

The first electrophysiological recordings from glial cells were obtained in invertebrate preparations (squid: Villegas et al., 1963; leech: Kuffler and Potter, 1964). The characteristics of these cells are typical of glial cells that have been studied in many *in vivo* and *in vitro* preparations (Trachtenburg and Pollen, 1970; Ransom and Goldring, 1973; Takato and Goldring, 1979; Gutnick et al., 1981; Burnard et al., 1990). In comparison to neurons, glial cells have a more negative resting membrane potential (E_m), a lower input resistance, and a faster time constant. The lower resting potential results from a higher selective potassium permeability of glial cell membranes compared to neurons. Glial cells also do not typically display action potentials or other regenerative potentials. It should be kept in mind that, although glia express inward Na^+ and Ca^{2+} currents, they appear passive during intracellular recordings when no pharmacological manipulations are used to decrease K^+ permeability (but see Sontheimer et al., 1992 for an exception).

The advent of patch-clamping techniques and preparations such as acutely isolated cells have revealed a greater complexity of glial membrane properties than previously suspected from intracellular recordings. This chapter reviews the evidence for multiple types of K^+ channels in glial and where possible provides a conceptual framework for a functional role.

ASTROCYTES

Historical Perspective

To date, astrocytes in culture have been the most widely used preparation to identify and characterize voltage-dependent channels. The advantages of culture preparations are evident: the cellular phenotype is relatively homogeneous, they can be maintained for long periods, there is no diffusion barrier and the cells are more amenable to voltage-clamping using whole-cell patch-clamping techniques. There are some disadvantages to only studying cells in culture because culture conditions influence cellular phenotype (Raff et al., 1983; Juurlink and Hertz, 1985), including channel expression (Barres et al., 1989). To circumvent these problems, techniques have been developed that allow fast and reliable acute isolation of astrocytes from mature tissue (Newman, 1985; Barres, 1992; MacVicar et al., 1992; Tse et al., 1992) (Figure 11-1). Alternatively, ion channels have recently been studied *in situ* using whole-cell patch-clamp techniques, which *allow* a low access resistance and reliable intracellular dialysis (Clark and Mobbs, 1992; Steinhäuser et al., 1992; Sontheimer and Waxman, 1993).

Astrocytes have been classified into two groups: (1) fibrous, which are commonly localized to white matter, and (2) protoplasmic, which are commonly found in gray matter (Peters et al., 1976). In cell culture, fibrous astrocytes are process-bearing while protoplasmic are flat and polygonal. Both types contain glial fibrillary acidic protein (GFAP). However,

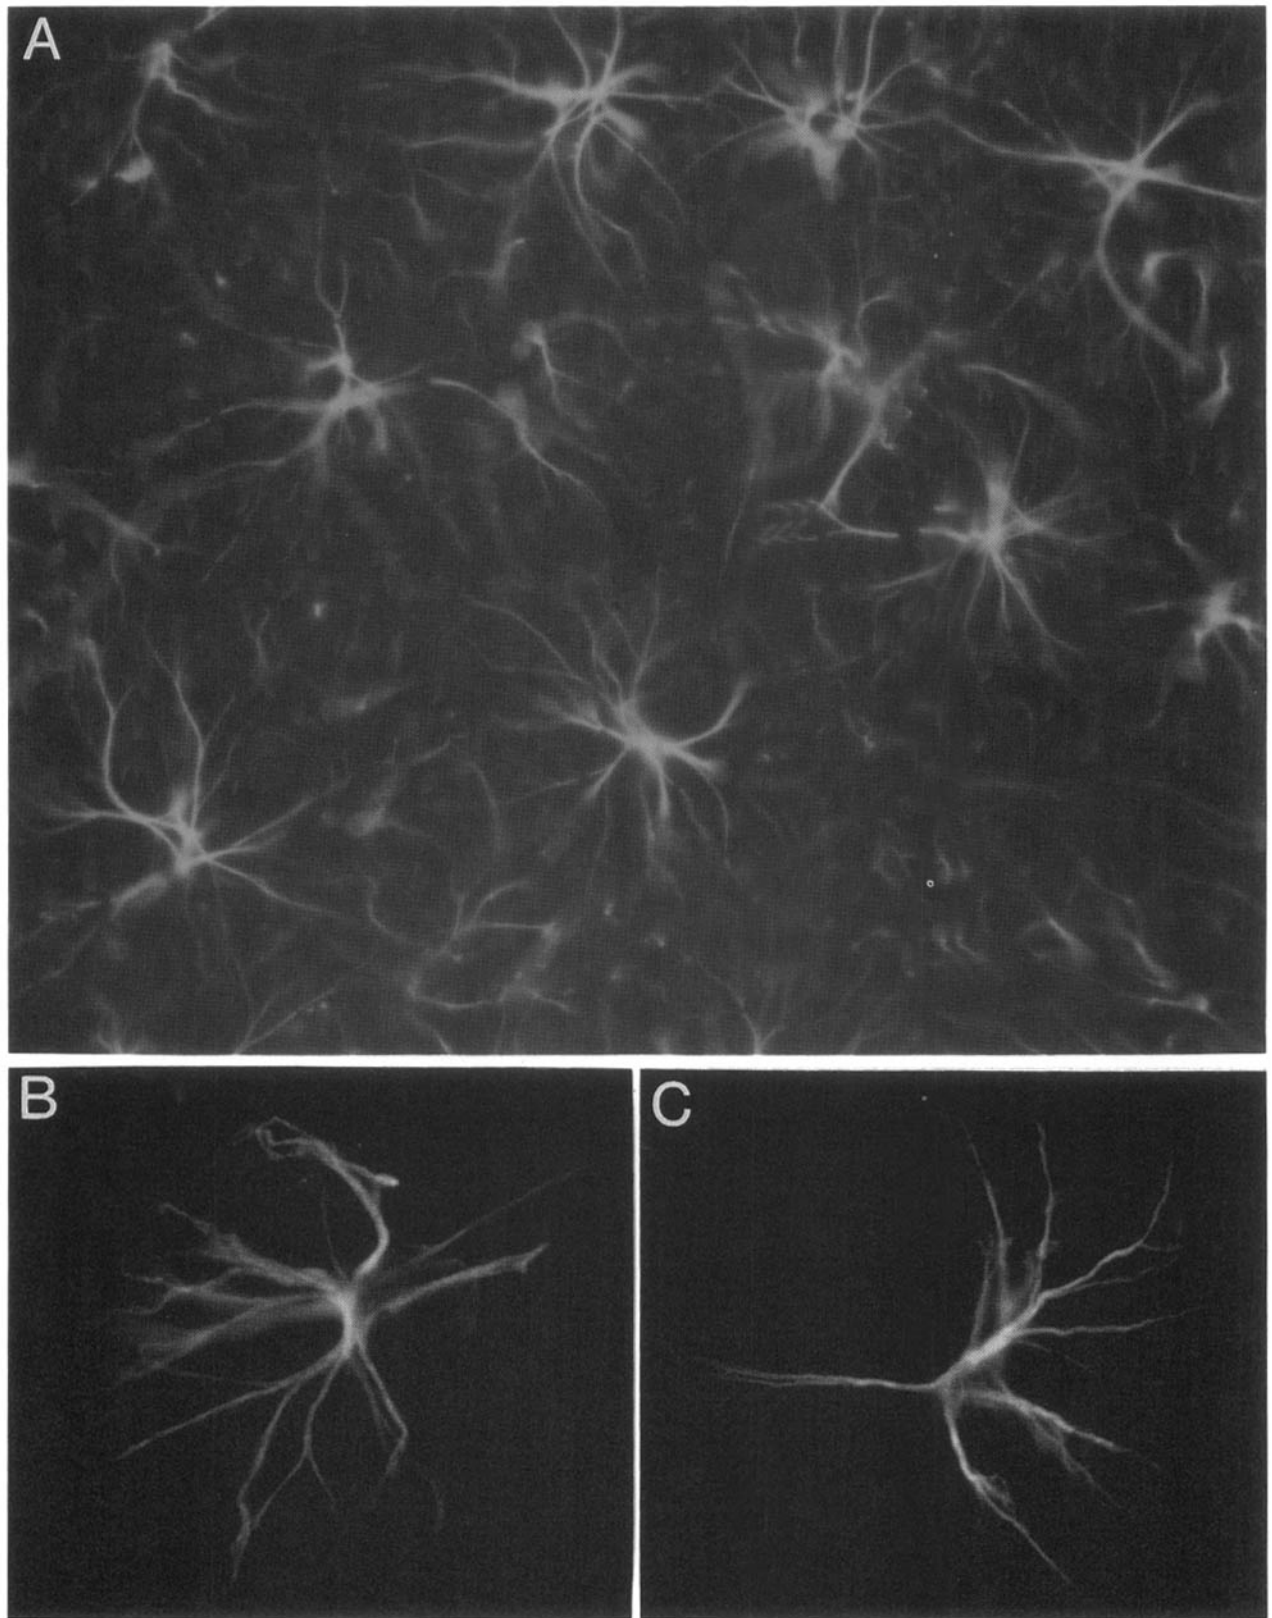

FIG. 11-1. Morphology of astrocytes immunohistochemically stained for glial fibrillary acidic protein (GFAP): Comparison between cells in the slice preparation or acutely isolated. (**A**) Astrocytes that were stained for GFAP in hippocampal slices after fixation and sectioning on a cryostat exhibited the typical stellate morphology. (**B, C**) Astrocytes acutely isolated using the technique described in MacVicar et al. (1992) still showed stellate morphology with good preservation of processes. [The photomicrograph in Figure A was supplied by Dr. L. Mudrick-Donnon.]

classification of astrocytes into either category may be difficult in several brain areas, including the hippocampus (Bignami et al., 1972). In cultures derived from the optic nerve, two astrocyte subtypes have been identified and termed type 1 and type 2 (reviewed by Barres et al., 1990c; Sontheimer, 1992). Type 2 are fibrous-like cells, which stain for both GFAP and the surface antigen termed A2B5, whereas type 1 are protoplasmic-like cells that are GFAP-positive and A2B5-negative. However, A2B5 staining of type 2 astrocytes has not been demonstrated *in vivo* in the optic nerve (Sontheimer, 1992). Thus, only where appropriate will we refer to protoplasmic as type 1 and fibrous astrocytes as type 2. Astrocytes obtained from acute isolation or in cultures devoid of A2B5 antigenicity will simply be designated by the brain region from which they were acquired.

Delayed Rectifier Potassium Channel

The delayed rectifier K^+ current (I_{DR}) was first described in the squid giant axon by Hodgkin and Huxley (1952; see Hille, 1992). This current is present in most excitable cells, and is primarily responsible for repolarization following spike discharge. Evidence for the expression of this channel in cultured astrocytes was obtained using whole-cell voltage-clamp techniques (Bevan and Raff, 1985; Bevan et al., 1985, 1987; Nowack et al., 1987; Barres et al., 1988, 1990a, 1990b; Sontheimer et al., 1992) (Figure 11-2). As in other cell types, the current is inactive at resting membrane potentials and is activated by depolarization. The activation threshold is typically -40 mV, and the conductance increase follows a sigmoidal time-course. Inactivation is minimal with maintained depolarization and deactivation following membrane repolarization occurs in a monoexponential fashion. Pharmacological depression is obtained by intracellular cesium, tetraethylammonium (TEA), or 4-aminopyridine (4-AP), or external TEA, 4-AP, or barium. In support of tissue culture studies, mature astrocytes obtained from enzymatic isolation techniques (Barres et al., 1990b; Tse et al., 1992) or investigated *in situ* (Steinhäuser et al., 1992; Sontheimer and Waxman, 1993) expressed macroscopic I_{DR} channels with similar kinetic and pharmacological properties.

Analysis of single K^+ channels in astrocytes has demonstrated remarkable diversity with variations in voltage-dependence, conductance, and pharmacological sensitivity (Figure 11-3) (e.g., 201 pS: Sonnhof and Schachner, 1986; 7 and 20 pS: Nowack et al., 1987; 20 and 100 pS: Barres et al., 1988; 45, 67, and 90 pS: Jalonen and Holopainen, 1989). These studies have not, however, demonstrated a single candidate for the channel underlying I_{DR}. At present, no individual channel corresponds to the well-characterized macroscopic current described above. However, it is possible that a variety of channel isoforms, each constructed of different subunits with diverse properties, contribute to the macroscopic voltage- and time-dependent currents.

The I_{DR} may be present throughout cell lineage, from initial precursor to mature astrocyte (Figure 11-4). Expression of the I_{DR} current was observed in a bipotent progenitor cell, termed O-2A, which differentiates into type 2 astrocytes and oligodendrocytes (Raff et al., 1983; Sontheimer et al., 1989; Barres et al., 1990a) and a multipotent EGF-responsive stem cell which differentiates into neurons, astrocytes, and oligodendrocytes (Fraser et al., 1992; Reynolds and Weiss, 1992; Weiss et al., 1992). The current is expressed into maturity (Steinhäuser et al., 1992; Tse et al., 1992; Sontheimer and Waxman, 1993); however, the current density may be reduced during development in a subpopulation of astrocytes (Sontheimer et al., 1992).

Transient A-Type Potassium Channel

The A-type K^+ current (I_A), first described in gastropod neuronal soma (Connors and Stevens, 1971), has been demonstrated in numerous excitable cell types where it modulates action potential frequency (Hille, 1992). The first description of I_A in a glial cell was obtained in type 2 astrocytes derived from optic nerve (Bevan and Raff, 1985; Bevan et al., 1987; Barres et al., 1988; Barres et al., 1990a) (Figure 11-2). The I_A, however, was not expressed in type 1 astrocytes cultured from the optic nerve (Bevan and Raff, 1985; Barres et al., 1990b). Subsequent reports revealed expression of I_A in astrocytes obtained from the cerebral cortex of rat (Bevan et al., 1985) and mouse (Nowack et al., 1987), salamander retina (Newman, 1985), and rat spinal cord (Sontheimer et al., 1992). As described in other cell types, the current activates and inactivates rapidly with depolarization. Neurons typically require a transient hyperpolarization to remove steady-state inactivation. However, the resting membrane potential of glial cells is so negative (-90 mV in 3 mM external K^+) that it is likely there is little steady-state inactivation of I_A at rest. The activation threshold is close to -40 mV and the conductance increase occurs in a sigmoidal fashion, much like the K_{DR}. The time-to-peak is voltage-dependent and with maintained depolarization the current undergoes voltage-dependent

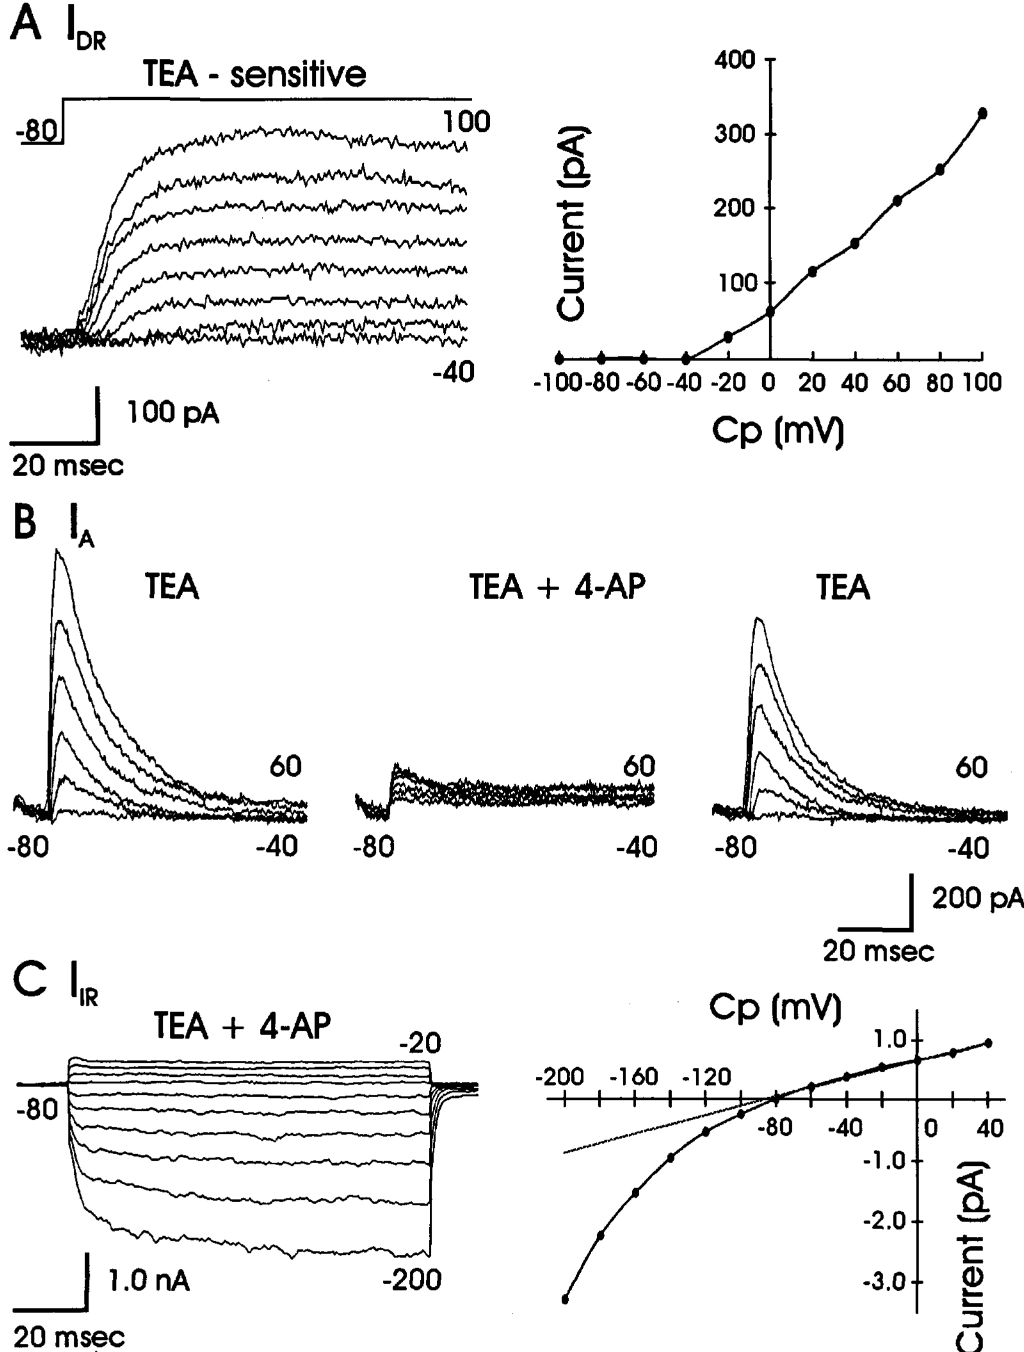

FIG. 11-2. Whole-cell voltage-clamp recordings from acutely isolated hippocampal astrocytes demonstrating the presence of I_{DR}, I_A, and I_{IR}. (A) Membrane potential was stepped from −40 mV to 100 mV from a holding potential of −80 mV in external solutions with or without tetraethylammonium (TEA, 40 mM). The outward current that was blocked by TEA (I_{DR}) is illustrated in the *left panel* and the *I-V* relationship of the peak outward current is plotted. There was no significant inactivation of the current over this time frame. The current had a threshold for turn-on of −40 mV. (B) In the presence of external TEA to block I_{DR} a rapidly inactivating outward current (I_A) was still observed. I_A turned on with a much faster time course than I_{DR} and inactivated almost completely over a time-course in which I_{DR} exhibited no decrement. I_A was totally blocked by external 4-aminopyridine (4-AP) in a reversible manner. (C) When I_{DR} and I_A were both blocked by external TEA and 4-AP an inward current (I_{DR}) was still evoked with hyperpolarizing voltage command pulses. I_{IR} did not exhibit appreciable inactivation at these potentials and turned on at potentials more negative than −80 mV.

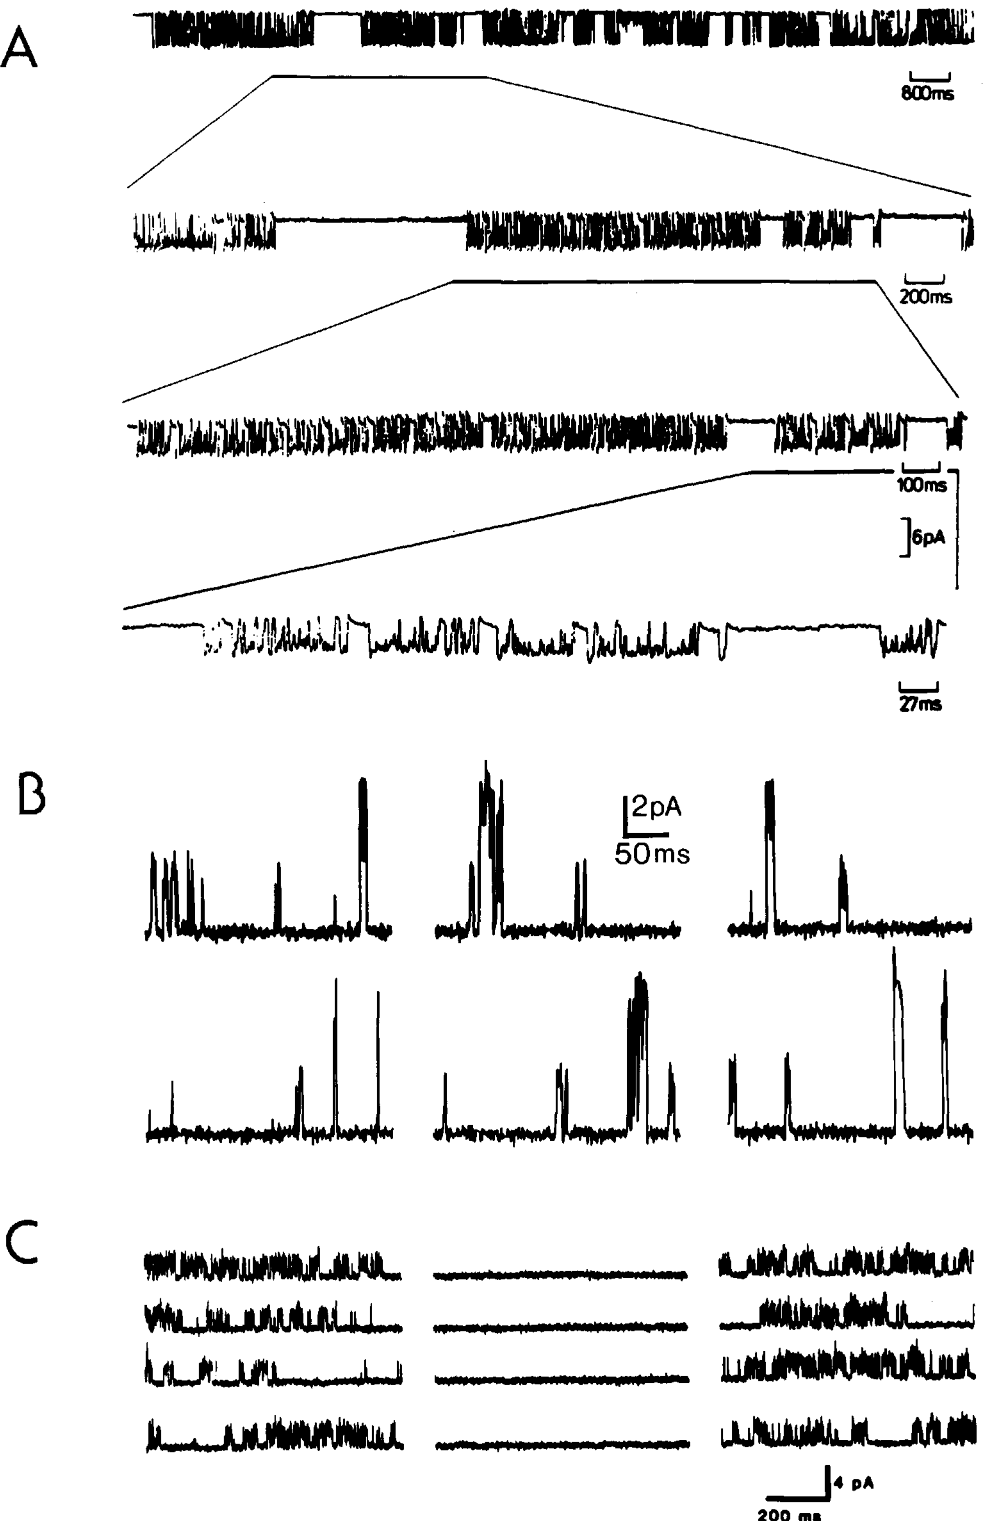

FIG. 11-3. Single-channel recordings from astrocytes illustrating voltage- and calcium-dependent K^+ channels. (A) Single K channel openings exhibited prolonged bursts in an inside-out patch recorded at −40 mV. Burst duration dramatically increased with depolarization. [From Sonnhof and Schachner (1986), with permission.] (B) Recordings from outside-out patches in another study revealed outward currents that appeared to constitute two classes. Mean current amplitudes were 1.6 and 3.7 pA. [From Nowak et al. (1987), with permission.] (C) Calcium-activated K^+ channels recorded from a type 1 cortical astrocyte in cell culture. This channel exhibited voltage and calcium sensitivity and was reversibly blocked by tetraethylammonium (second panel). [From Quandt and MacVicar (1986), with permission.]

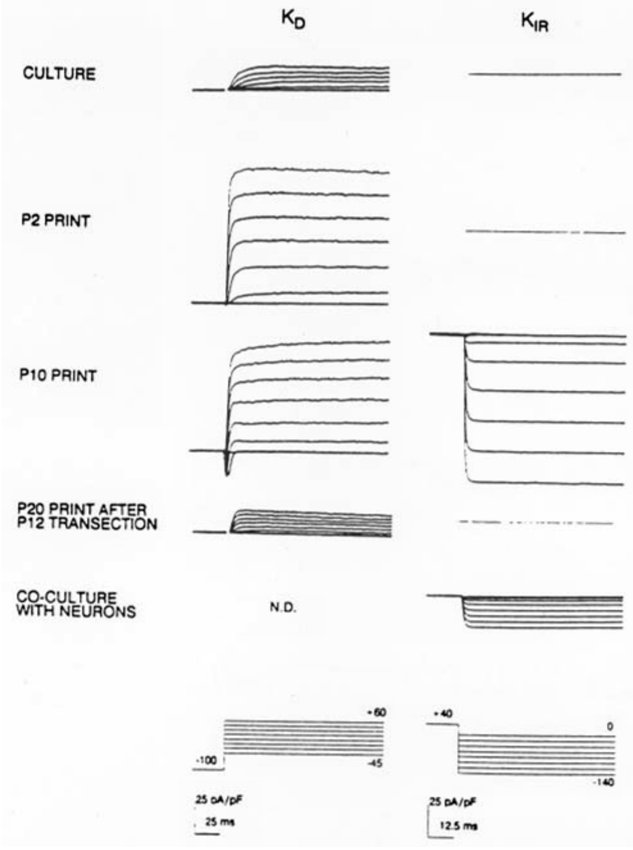

FIG. 11-4. Variability of the expression of I_{DR} and I_{IR} in type 1 astrocytes during development and in different culture conditions. Whole-cell voltage-clamp recordings are illustrated from astrocytes either in culture or prints obtained on postnatal day 2 (*P2*) or day 10 (*P10*). Currents are also illustrated from cells printed on *P20* after optic nerve transection on *P12* and from astrocytes cocultured with neurons for 36 hours. The expression of both I_{DR} and I_{IR} were enhanced during development and were altered by coculture with neurons. [From Barres et al. (1990b), with permission.]

inactivation with a monoexponential time course. I_A is blocked by intracellular cesium or 4-aminopyridine or external 4-AP (at lower concentrations than I_{DR}) and is relatively insensitive to external tetraethylammonium. Since the activation thresholds of the I_{DR} and the I_A currents are similar, current separation and isolation requires subtraction procedures using voltage paradigms (Barres et al., 1988; Sontheimer et al., 1992; Tse et al., 1992; Sontheimer and Waxman, 1993) or pharmacological manipulations (Nowack et al., 1987; Sontheimer et al., 1992; Tse et al., 1992). In support of the tissue culture studies mentioned above, mature type 1 astrocytes obtained from the optic nerve using enzymatic isolation techniques did not express I_A channels (Barres et al., 1990b). However, mature hippocampal astrocytes obtained from enzymatic isolation techniques (Tse et al., 1992) or investigated *in situ* (Steinhäuser et al., 1992; Sontheimer and Waxman, 1993) expressed macroscopic I_A channels.

As with the I_{DR}, single-channel analysis has not yet identified a microscopic candidate that could underlie the macroscopic I_A current (Sonnhof and Schachner, 1986; Jalonen and Holopainen, 1989). Inactivation of I_A is thought to result from movement of a peptide ball that occludes the intracellular side of the channel pore via electrostatic and hydrophobic interactions (Hoshi et al., 1990; Zagotta et al., 1990). Since excised patches were used to identify single astrocytic K^+ channels, it is possible that the inactivation gate was disrupted or, alternatively, the inactivation particle in astrocytes may be a cytoplasmic constituent.

As with the delayed rectifier, the I_A currents may be present throughout cell lineage. Expression of the I_A was observed in bipotent progenitor cells (Raff et al., 1983; Sontheimer et al., 1989; Barres et al., 1990a) and multipotent EGF-responsive stem cells (Fraser et al., 1992; Reynolds and Weiss, 1992; Weiss et al., 1992), which may differentiate into astrocytes. The I_A was also expressed in type 2 astrocytes derived from optic nerve (Bevan and Raff, 1985; Barres et al., 1988) or from spinal cord (Sontheimer et al., 1992). The current is expressed into maturity (Steinhäuser et al., 1992; Tse et al., 1992; Sontheimer and Waxman, 1993); however, the current density may be reduced throughout development in a subpopulation of astrocytes (Sontheimer et al., 1992). The I_A may be developmentally regulated, since the activation and inactivation kinetics of mature astrocytes are at more positive potentials than precursors. For example, bipotent progenitor cells and multipotent EGF-responsive stem cells have inactivation midpoints at -95 mV (Sontheimer et al., 1989) and -74 mV (Fraser et al., 1992a), respectively, while enzymatically isolated astrocytes from mature hippocampus have inactivation midpoints of -60 mV (Tse et al., 1992). It should be noted that space-clamp error may be more pronounced in voltage-clamp studies of astrocytes acutely isolated or in slice preparations. This could contribute to the observed differences in activation and inactivation potentials.

Calcium-Activated Potassium Channel

Two major subtypes of Ca^{2+}-activated K^+ channels ($I_{K(Ca)}$) have been identified based on single-channel conductance, Ca^{2+} sensitivity, voltage-dependence, and pharmacological blockade (Latorre et al., 1989). The maxi $I_{K(Ca)}$ channel (or BK) is characterized by a large conductance (130 to 300 pS) and blockade

by extracellular tetraethylammonium, charybdotoxin, or iberiotoxin, whereas the mini $I_{K(Ca)}$ channel (or SK) is characterized by a smaller conductance (<80 pS) and blockade by TEA or apamin. The presence of $I_{K(Ca)}$ channels on astrocytes was speculated following the demonstration of voltage-activated Ca^{2+} channels (MacVicar, 1984). $I_{K(Ca)}$ currents were first demonstrated in glial cells using whole-cell voltage-clamp recordings of dissociated retinal Müller cells (Newman, 1985). The outward current was activated by depolarization and could be depressed by external TEA or blockade of voltage-dependent Ca^{2+} influx. Single-channel recordings from rat (Quandt and MacVicar, 1986) (Figure 11-3) or mouse (Nowack et al., 1987) cerebral astrocytes have revealed two channel subtypes with properties corresponding to SK (25 pS) and BK (230 pS). Both channels exhibited Ca^{2+} and voltage sensitivity and depression by extracellular TEA.

Expression of the BK current was observed in both bipotent progenitor cells (Raff et al., 1983; Barres et al., 1990a) and mature type 2 astrocytes (Barres et al., 1988), indicating that it may be present throughout cell lineage. The $I_{K(Ca)}$ in both cell types was composed of sustained and transient components and was sensitive to external charybdotoxin or changes in intracellular Ca^{2+} buffering. A BK current was also described in multipotent EGF-responsive stem cells in experiments using the perforated-patch technique to inhibit intracellular dialysis (Fraser et al., 1992; Reynolds and Weiss, 1992; Weiss et al., 1992). Under these conditions, the current displayed weak voltage-dependent inactivation and was sensitive to external iberiotoxin or TEA. Mature type 1 astrocytes obtained from enzymatic dissociation revealed K^+ currents that were sensitive to intracellular Ca^{2+} buffering; however, the K^+ currents were not depressed by external charybdotoxin (Barres et al., 1990b). Thus, the $I_{K(Ca)}$ in this noncultured cell type may be of a type other than the BK channels. Mature astrocytes in kainate-lesioned hippocampal slices appeared to express the SK channel, since a portion of K^+ permeability was sensitive to apamin (Burnard et al., 1990).

Inward Rectifier Potassium Channel

The inward rectifier K^+ channel (I_{IR}), first described by Katz (1949; see Hille, 1992) in muscle cells, is a conductance that increases with hyperpolarization. The first evidence for a glial inward rectifier was obtained using whole-cell voltage-clamp recordings of acutely dissociated retinal Müller cells (Newman, 1985). It was soon clear that the I_{IR} was widely distributed in cultured cells; expression was reported in type 1 (Barres et al., 1990a) and type 2 (Barres et al., 1990b) astrocytes from optic nerve, type 2 astrocytes from rat cortex (Sontheimer et al., 1989), astrocytes from mouse cerebral cortex (Walz and Hinks, 1987), and astrocytes from rat spinal cord (Sontheimer et al., 1992). Expression was detected in astrocytes obtained by enzymatic isolation (Barres et al., 1990b; Tse et al., 1992) (Figure 11-2) or recorded *in situ* (Steinhäuser et al., 1992; Sontheimer and Waxman, 1993). Several properties of the I_{IR} channel are unique and well-conserved, including voltage-dependence of channel activation and conductance, dependence on $[K^+]_0$ and sensitivity to external cesium (Barres et al., 1990a, 1990b) or barium (Sontheimer et al., 1989; Steinhäuser et al., 1992; Tse et al., 1992). However, there appears to be heterogeneity in regard to voltage-dependent inactivation. For example, in a subset of astrocytes, I_{IR} undergoes voltage-dependent inactivation at hyperpolarizing potentials (Steinhäuser et al., 1992; Sontheimer and Waxman, 1993), whereas in other populations the current is noninactivating (Barres et al., 1990a, 1990b; Sontheimer et al., 1992; Tse et al., 1992). The I_{IR} probably plays a dominant role in setting the astroglial resting membrane potential. This is the only K^+ channel type described so far with a large open probability near the equilibrium potential for K^+. Also external Cs^+ or Ba^{2+} depolarize glial cells most likely by blocking I_{IR}. At the microscopic level, single-channel records obtained from acutely isolated retinal Müller cells have revealed heterogeneity of I_{IR} channels with different conductances ranging from 40 to 105 pS in symmetrical K^+ (Brew et al., 1986; Nilius and Reichenbach, 1988).

The I_{IR} channels may be present throughout cell lineage in at least one astrocytic subtype from optic nerve. Expression of I_{IR} was observed in bipotent progenitor cells (Barres et al., 1990a), and current expression was retained in mature type 2 astrocytes (Barres et al., 1988; 1990b). However, the current was not expressed in bipotent progenitor cells obtained from rat brain (Sontheimer et al., 1989) or multipotent EGF-responsive stem cells from mouse striatum (Fraser et al., 1992; Reynolds and Weiss, 1992). The macroscopic current was expressed later in development in both type 1 astrocytes enzymatically obtained from optic nerve (Barres et al., 1990b) and astrocytes cultured from rat spinal cord (Sontheimer et al., 1992). The currents were observed in mature hippocampal astrocytes obtained by enzymatic isolation (Tse et al., 1992) or recorded *in situ* (Steinhäuser et al., 1992; Sontheimer and Waxman, 1993).

The Leak Current

Initial electrophysiological studies on astrocytes using conventional microelectrode techniques revealed a linear current-voltage relation, which reversed close to the resting membrane potential (reviewed by Walz, 1989). Since the resting membrane potential corresponds to the K^+ equilibrium potential, it was assumed that the large K^+ permeability was due to a nonrectifying leak current. Recently, new electrophysiological techniques have been developed, which suggest that, as in neurons, the true electrotonic behavior of glial cells may be masked by conventional intracellular recording. These methods include whole-cell and perforated patch techniques (Hamill et al., 1981; Horn and Marty, 1988). Neurons have much higher values for input resistance when recorded using whole-cell patch-clamp methods, as compared to intracellular recordings using sharp microelectrodes. Comparisons suggest that sharp microelectrodes induce a leak conductance three times greater than that measured by whole-cell patch-clamping (Staley et al., 1992). This leak conductance is generated by membrane damage surrounding the impalement and an increase K^+ permeability evoked by cytosolic elevations in sodium and calcium. The perforated patch method, which does not allow intracellular dialysis, has further confirmed this point (Spruston and Johnston, 1992). Considering the relatively small diameter of an astrocytic soma, one would expect even a greater leak conductance induced by impalement. At present, no quantitative study of the electrotonic structure of astrocytes has been performed in a slice preparation using these techniques. However, these methods may reveal a surprisingly large input resistance, not previously assumed. The current-voltage relation of astrocytes *in vivo* may be far from linear, considering the wide range of voltage-gated channels expressed (Sontheimer, 1992; Sontheimer and Waxman, 1993). Finally, if the electrotonic structure of the astroglial syncytium has been misinterpreted, astrocytes may play a greater role in K^+ siphoning than previously believed.

Spatial Distribution of Channels

It has been shown in retinal Müller cells that particular regions of glial membranes may contain higher densities of K^+ channels or K^+ channels with a greater conductance (see Chapter 47, this volume). Experiments using focal K^+ ejection have demonstrated that the magnitude of the endfoot responses are exceptionally large, indicating a greater K^+ conductance level (Newman, 1984). In support of these studies single channel analysis has demonstrated that I_{IR} channels are distributed unevenly across the membrane. The vitreal process and endfoot contain a greater density of I_{IR} channels (Brew et al., 1986). In fact, removal of the endfoot results in a dramatic increase in cellular resistance (reviewed by Newman, 1987). These studies indicate that 95% of the total conductance lies in or around the endfoot removed by a microdissection procedure. In mammalian retinal glial cells, a second nonrectifying K^+ channel was found, with a much greater single-channel conductance to facilitate K^+ efflux (Nilius and Reichenbach, 1988). This precise segregation of K^+ influx channels (I_{IR}) and efflux channels may allow astrocytes to more efficiently clear $[K^+]_0$ from areas of accumulation around active neurons (spatial buffering) or augment the activity of K^+ transporters (Walz, 1989).

Other Relevant Currents

To maintain electroneutrality, the movement of K^+ across biological membranes is often accompanied or restricted by movements of Cl^- (Boyle and Conway, 1941). In astrocytes, the Cl^- equilibrium potential is positive to the resting membrane potential. In fact, the equilibrium potential may be as positive as -35 mV due to the activity of two inwardly directed transporters, a Na^+-K^+-$2Cl^-$ cotransport and a Cl^--HCO^-_3 exchange (Kettenmann, 1990; Kimelberg, 1990). The first demonstration of a Cl^- current in astrocytes was obtained via whole-cell voltage-clamp recordings of macroscopic currents (Bevan et al., 1985). Ionic identification was based on analysis of reversal potentials and ion substitution experiments. Subsequent studies were unable to identify a macroscopic Cl^- current, although single channels were identified in excised patches at the microscopic level (Barres et al., 1988; 1990b). The discrepancy between the lack of observable macroscopic currents and the presence of single channel currents in excised patches suggest that channel activity is regulated by cytoplasmic factors. Further evidence for this phenomenon is inferred by the lack of single-channel recordings in the cell-attached recording mode and their ensuing appearance several minutes following excision (Sonnhof, 1987). Nonetheless, excised recordings have revealed two channel subtypes based on conductance levels. The large conductance channels are 260 (Barres et al., 1988), 385 (Nowack et al., 1987) or 465 pS (Sonnhof, 1987) and open in response to depolarization. The activation threshold is close to -40 mV, much like I_{DR} and I_A. The small conductance channels are 5

(Nowack et al., 1987), 25 or 60 pS (Barres et al., 1990b), and at least one subtype of the small conductance channels open with hyperpolarization (Nowack et al., 1987). A Cl^- flux may also be initiated by opening ligand-gated channels. Astrocytes in culture (Bormann and Kettenmann, 1988) or isolated following enzymatic treatment (Fraser et al., 1995) express $GABA_A$ receptors which mediate a large Cl^- conductance.

Elevations in cytosolic Ca^{2+}, from influx through either voltage- or ligand-gated channels, can regulate K^+ flux across the cell membrane (Latorre et al., 1989). The first report of Ca^{2+} channels in astrocytes came from current-clamp studies (MacVicar, 1984). Subsequent reports, using whole-cell voltage-clamp techniques, identified both low-voltage activated (Barres et al., 1988; 1990b; Puro and Mano, 1991) and high-voltage activated Ca^{2+} channels (Newman, 1985; Barres et al., 1988; 1990b; MacVicar and Tse, 1988; Corvalan et al., 1990; Puro and Mano, 1991). Most of these studies were on cultured astrocytes exposed to dBcAMP (MacVicar, 1984) or serum (Barres et al., 1989); however, a high-threshold Ca^{2+} influx was recently revealed in enzymatically isolated hippocampal astrocytes (Duffy and MacVicar, 1994). An elevation in intracellular Ca^{2+} may also occur by activation of ligand-gated receptors. An obvious transmitter candidate is glutamate. Indeed, cultured hippocampal astrocytes (Glaum et al., 1990; Cornell-Bell et al., 1990) or Bergmann glial cells studied in either culture (Burnashev et al., 1992) or *in situ* (Müller et al., 1992) express Ca^{2+}-permeable AMPA-kainate receptors.

OLIGODENDROCYTES AND SCHWANN CELLS

While many functions have been attributed to glial cells, a functional role is most clearly defined for myelinating peripheral nervous system Schwann cells and central nervous system oligodendrocytes. Myelination restricts Na^+ influx to short axon segments (nodes of Ranvier), thereby greatly increasing action potential velocity and reducing energy consumption for ion redistribution (Hille, 1992). Several observations, however, indicate that these cells have other functions. First, many Schwann cells and oligodendrocytes do not produce myelin, but rather extend processes which interdigitate between many small diameter axons. Second, both Schwann cells (Evan et al., 1985, 1992; Jahromi et al., 1992) and oligodendrocytes (Vartanian et al., 1988; Butt and Tutton, 1992) express neurotransmitter receptors, which may allow chemical communication with axons. Third, these cells express voltage-gated ionic channels, the most prominent of which are several subtypes of K^+ channels. These channels may confer several important functional attributes to oligodendrocytes and Schwann cells, including spatial buffering of interstitial K^+ ions and the modulation of cell proliferation during early development and following nerve degeneration.

Potassium Channel Expression and Modulation in Oligodendrocytes

As in astrocytes, the membranes of oligodendrocytes are predominately permeable to K^+. In oligodendrocytes from explant cultures of mouse spinal cord, Kettenmann et al. (1983b) observed that E_m changed 61 mV per tenfold change in $[K^+]_0/[K^+]_i$, consistent with the Nernst relation for an exclusively K^+-permeable membrane. Similarly, the E_m-$[K^+]_0$ relation in oligodendrocytes from the intact optic nerve was consistent with a K^+-selective membrane (Butt and Tutton, 1992), suggesting that oligodendrocyte *in situ* have similar biophysical properties. Methods for culturing relatively pure oligodendrocyte populations (McCarthy and De Vellis, 1980) and patch-clamping at both the whole-cell and single channel levels (Hamill et al., 1981) have greatly facilitated the description of the K^+ currents and channels which underlie this large membrane K^+ permeability. These studies have revealed that cells of the oligodendrocyte lineage express most of the K^+ channel subtypes that have been described in neurons and astrocytes, including I_{IR}, I_{DR}, I_A, and $I_{K(Ca)}$.

The specific complement of K^+ channels expressed by oligodendrocytes is highly variable, depending on species, culture methods, and developmental stage. For example, cultured ovine oligodendrocytes (Soliven et al., 1988a, 1988b), mouse oligodendrocytes (Sontheimer and Kettenmann, 1988) and serum-free cultures from rat optic nerves (Barres et al., 1990a) expressed all three K^+ currents simultaneously. Rat optic nerve cultures containing serum expressed either I_{DR} and I_{IR} (Barres et al., 1990b) or only I_{IR} (Barres et al., 1988). On the other hand, oligodendrocytes cultured from mouse brain (Sontheimer et al., 1989b) and cultured adult bovine oligodendrocytes (McLarnon and Kim, 1989b) were found to express only I_{IR}. Likewise, oligodendrocytes cultured from adult humans expressed a prominent I_{IR}, while outward channel density was quite low (McLarnon and Kim, 1989a). Oligodendrocytes cultured from fish optic nerve, however, express both outward K^+ currents but not I_{IR} (Hoppe et al., 1991; Glassmeier et al., 1992). A completely passive *I-V* relation, indicating no (measurable) voltage-dependent ionic

channels, was reported in cultured oligodendrocytes from rat optic nerve (Bevan and Raff, 1985). There is also considerable variability in oligodendrocyte ionic channel phenotype within a given culture (Sontheimer and Kettenmann, 1988).

Oligodendrocytes *in situ* also express voltage-gated K^+ currents (Barres et al., 1990a; Berger et al., 1991), and again, ionic channel expression pattern is heterogeneous. Barres et al. (1990a) found that oligodendrocytes, acutely isolated from postnatal day 7 rat optic nerve, expressed all three current components. Conversely, Berger et al. (1991) found mainly I_{DR} in oligodendrocytes from slices of postnatal days 6 to 8 mouse corpus callosum, while in older animals (postnatal days 10 to 13), no voltage-gated currents were reported.

The influence of developmental plasticity has been thoroughly investigated in cultures of developing oligodendrocyte precursors (Soliven et al., 1988b; Sontheimer et al., 1989; Barres et al., 1990a). By correlating ionic channel expression pattern with the development changes in surface antigen expression, these studies have found that channel phenotype becomes less complex as oligodendrocyte differentiation progressed. In one such study, the A2B5 immunopositive oligodendrocyte-type 2 astrocyte precursor cell (O-2A cell) (Raff et al., 1983) expressed I_{DR} and I_A, as well as a $[Ca^{2+}]_i$-dependent K^+ current ($I_{K(Ca)}$) and I_{Na} (Sontheimer et al., 1989). After commitment to the oligodendroglia lineage, however, all these currents were downregulated and I_{IR} density increased. In a similar study, I_{DR} and I_{IR} remained in mature cells (Barres et al., 1990a). Changes in channel expression were also observed in aging oligodendrocyte cultures (Soliven et al., 1988b); outward currents were downregulated slightly, while I_{IR} increased significantly over the first 10 days after plating.

Potassium Current Kinetics and Single-Channel Properties in Oligodendrocytes

At the level of the macroscopic current, I_{DR} and I_A activate at potentials positive of −50 to −40 mV (Barres et al., 1990; Sontheimer and Kettenmann 1988; Soliven et al., 1988a, 1988b; Hoppe et al., 1991; Glassmeier et al., 1992). Like the neuronal I_A, oligodendrocyte I_A shows voltage-dependent inactivation (inactivation rate increasing with depolarization) and sensitivity to external 4-aminopyridine (Soliven et al., 1988a, 1988b; Sontheimer et al., 1989; Glassmeier et al., 1992). I_A is largely inactivated at resting E_m. In one study (Soliven et al., 1988b) I_A showed approximately 80% inactivation at −60 mV, suggesting that activation only occurs with depolarization from a relatively hyperpolarized E_m. Conversely, I_{DR} shows little voltage-dependent inactivation and is more sensitive to external TEA. I_{IR} is activated by hyperpolarization below −70 to −80 mV, and current magnitude increases with elevations in $[K^+]_0$. I_{IR} is, in most instances, noninactivating or slowly inactivating. However, at very negative potentials, inactivation of I_{IR} has been shown (Barres et al., 1988).

The first measurement of single-channel currents in oligodendrocyte revealed that these cells expressed a prominent voltage-independent, high-conductance (70 pS) K^+ channel, which may account for the large resting K^+ conductances (gk) of oligodendrocyte membranes (Kettenmann et al., 1982). An unequivocal link between many channel subtypes measured at the single-channel level and identified macroscopic currents has only been firmly established for I_{IR}. With depolarization, I_{IR} open channel probability and mean channel open time increase. However, conductance is minimal. Hyperpolarizing the membrane to values more negative than E_K results in short high-conductance openings, and conductance increases with $[K^+]_0$. Single-channel behavior is similar across mammalian oligodendrocytes. In cultured adult human oligodendrocytes, single-channel conductance was 29 pS in 140 mM $[K^+]_0$ (McLarnon and Kim, 1989b). Nearly identical channel activity (30 pS in 130 mM K^+) was measured in cultured rat oligodendrocytes from optic nerve (Barres et al., 1988) and in cultured ovine cells (28 pS in 140 mM K^+) (Soliven et al., 1989). In addition, rat oligodendrocytes also expressed a higher conductance I_{IR} channel of 120 pS.

Functions of Oligodendroglial Potassium Channels

The activation range of macroscopic I_{DR} and I_A implies that these conductances would be most active during very large depolarizations, possibly in response to neurotransmitter stimulation (Barres et al., 1990a, 1990b; Butt and Tutton 1992) or in immature cells which express Na channels (Barres et al., 1990a, 1990b; Sontheimer et al., 1989). The biophysical properties of I_{IR} suggest, more clearly, several possible functional roles in oligodendrocyte physiology. I_{IR} channels are most active near the resting E_m, implying that I_{IR} must play a dominant role in setting resting E_m. Also, because K^+ influx increases as the difference between E_m and E_K increases, I_{IR} could, in manner analogous to that proposed for astrocytes, allow oligodendrocytes to spatially buffer the accumulation of K^+ ions resulting from action potential repolarization. In fact,

white matter $[K^+]_0$ may increase substantially during nerve excitation, necessitating strong K^+ buffering capacity. In corpus callosum oligodendrocytes, the reversal potentials of tail currents following depolarizating pulses became more positive as pulse duration was increased, indicative of a depolarizing shift in E_K concomitant with interstitial K^+ accumulation (Berger et al., 1991). The actual role of oligodendrocytes in spatial buffering, however, is still uncertain. Such a process would be greatly facilitated by spatial segregation of rectifying and nonrectifying ion channels (i.e., K^+ influx and efflux pathways), but unlike Müller cells of the retina (Brew et al., 1986; Newman, 1986; Nilius and Reichenbach, 1988) and mammalian Schwann cells (Wilson and Chiu, 1990b) channel segregation has not been demonstrated in oligodendrocytes. Moreover, spatial buffering mediated by K^+ channels (as opposed to K^+ transporters) depends on electrotonic coupling between cells to form an electrotonic syncytium. While oligodendrocytes were electrotonically coupled to neighboring oligodendrocytes (Kettenmann et al., 1983a; Kettenmann and Ransom, 1988) and astrocytes in coculture (Ransom and Kettenmann, 1990), the coupling ratio was much smaller than that between astrocytes. Thus, it has been suggested that white matter astrocytes are more important than oligodendrocytes in buffering K^+. On the other hand, cultured rat oligodendrocytes did express a very large conductance I_{IR} channel (Barres et al., 1988), and it is this channel which has been postulated to be of special importance for K^+ buffering in mammalian retina (Nilius and Reichenbach, 1988).

Oligodendrocytes may also actively accumulate K^+ ions by KCl influx. Oligodendrocytes express large conductance anion channels (Barres et al., 1988), which are a prerequisite to this process. Moreover, $[K^+]_0$-dependent $[K^+]_i$ increases have been demonstrated in cultured oligodendrocytes with $[K^+]_i$-sensitive microelectrodes (Kettenmann et al., 1983b) and radioactive tracer flux (Hertz et al., 1990).

K^+ currents may modulate oligodendrocyte differentiation, as maturation is accompanied by stereotypic changes in ionic channel expression patterns (Soliven et al., 1989; Sontheimer et al., 1989; Berger et al., 1991) and channel modulation can influence differentiation (Soliven et al., 1988a, 1989). In cultured ovine oligodendrocytes, transient and sustained outward K^+ currents developed within 1 to 2 days after plating, while I_{IR} did not appear until several days later (Soliven et al., 1988a). The outward current was inhibited by analogues of cAMP, the adenylate cyclase activator forskolin, β-adrenergic receptor stimulation (which is coupled to adenylate cyclase), and the protein kinase C activator phorbol esters. *In vitro*, these second messenger systems are also activated by substrate attachment, which in turn leads to myelinogenesis (Vartanian et al., 1986). Thus, there may be a causal link between ionic channel expression and myelinogenesis.

Finally, while variability of ionic channel expression pattern is well described, less clear is the extent to which these differences reflect divergence in cell function. However, an intriguing hint is provided by fish oligodendrocytes. Unlike many oligodendrocytes, these cells do not express I_{IR} (Hoppe et al., 1991; Glassmeier et al., 1992). In this regard, they are similar to mature Schwann cells of higher vertebrates. In addition, these cells share several surface antigens with Schwann cells (Jeserich and Waehneldt, 1987). Significantly, like peripheral Schwann cells and unlike most central nervous system oligodendrocytes, these cells may provide an environment conducive to axon regeneration (Bastmeyer et al., 1991).

Potassium Channel Expression and Modulation in Schwann Cells

Voltage-dependent K^+ channels were first reported on cultured Schwann cells by Chiu et al. (1984). Like oligodendrocytes, Schwann cells express an array of K^+ channel types with expression patterns varying markedly between species. Howe and Ritchie (1988) observed two pharmacologically separable outward K^+ current components in cultured rabbit Schwann cells, one sensitive to both 4-AP and TEA, and one largely resistant to 4-AP but TEA-sensitive. This 4-AP-sensitive current has been further differentiated into two subcomponents, a low-threshold current, sensitive to α-dendrotoxin, and a higher-threshold current that had a lower 4-AP-sensitivity, was insensitive to α-dendrotoxin, and showed slower activation with depolarization (Baker et al., 1993). However, neither 4-AP-sensitive component resembled I_A, the main 4-AP-sensitive I_K in other glia. On the basis of their slower inactivation kinetics and greater TEA-sensitivity, these channels resemble axonal delayed rectifiers (I_{DR}). A 4-AP-sensitive, inactivating (I_A-like) current has, however, been reported in Schwann cells from mouse dorsal root ganglion along with a less 4-AP-sensitive, more TEA-sensitive sustained current (Amedee et al., 1991). Schwann cells also express an inwardly rectifying current (I_{IR}) (Konishi, 1990b, 1992; Wilson and Chiu 1990b), the expression of which is sensitive to the developmental state (see below). The relative density of these currents vary considerably between species.

Konishi (1989) compared outward K^+ currents measured from rabbit, rat, mouse, and human cultured Schwann cells. Transient currents were virtually absent in rabbit but dominated in rat. Mouse and human Schwann cells expressed both components. The I_K in acutely isolated mouse Schwann cells does not have a large inactivating component, however (Konishi, 1990a, 1990b; Wilson and Chiu 1990a), so I_{DR} and I_{IR} are the dominant currents expressed *in situ.*

The ionic channel phenotype of Schwann cells is very sensitive to the developmental state and follows different developmental patterns, depending on whether cells are myelinating or nonmyelinating (Figure 11-5). In one culture study, mature myelinating cells did not express measurable voltage-gated gk, while nonmyelinating cells expressed a prominent I_{DR} (Konishi, 1990a). Similarly, cells acutely isolated from embryonic mouse nerve (before the onset of myelination) expressed I_{DR} (Konishi, 1990a, 1990b). However, in neonatal nerve, whole-cell gk of myelinating cells increased and E_m hyperpolarized. These biophysical changes were due to the expression of a Ba^{2+}-sensitive I_{IR} in addition to I_{DR}. Over the several weeks following birth, both K^+ currents were downregulated in myelinating cells, and E_m became positive to E_K. A similar patter of rapid up- and downregulation of I_{DR} and I_{IR} was observed in myelinating cells from rat sciatic nerve (Wilson and Chiu, 1990a). In nonmyelinating cells, on the other hand, neither current magnitude (of I_{DR}) nor E_m changed significantly with age (Konishi, 1990a, 1990b).

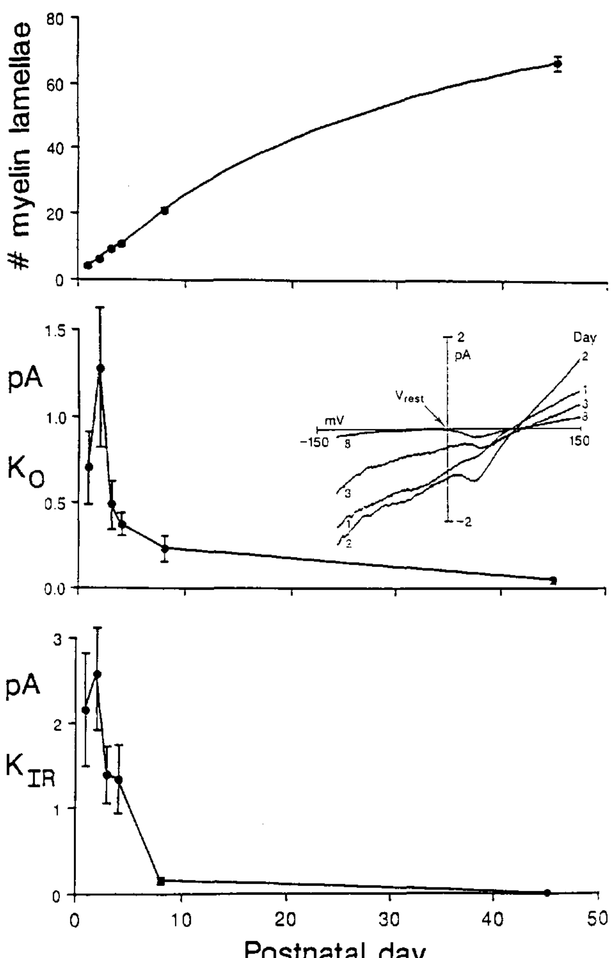

FIG. 11-5. The expression of K^+ currents in Schwann cells changes during development and diminishes during myelination. Current amplitudes were determined from the ramp *I-V* relationship (*insert*). The number of myelin lamellae was determined in electron microscopy by counting the number of major dense lines in cells associated with only one axon. Myelin counts were obtained from nerves contralateral to those used in electrophysiology. [From Wilson and Chiu (1990a), with permission.]

Many aspects of this developmental pattern are recapitulated following nerve transection (Chiu, 1988; Chiu and Wilson, 1989). In Schwann cells surrounding the distal nerve stump, ionic channel expression changed depending whether cells were myelinating or nonmyelinating. In nonmyelinating cells, I_K was slightly reduced and E_m did not change, while in myelinating cells, the TEA-sensitive outward K^+ current was upregulated, and E_m hyperpolarized. Thus, myelinating Schwann cells reverted to a phenotype similar to that observed in neonatal nerve when myelin is first produced.

An important question which arises from these studies is whether the apparent downregulation of ionic channels is due to fewer membrane channels or to migration of channels from the soma (the site of whole-cell voltage-clamp recordings) to less accessible areas of the cell membrane. To address this question, Chiu and Wilson (1990b) made cell-attached patch recordings from adult rat Schwann cells at the paranodal region. Significantly, both I_{DR} and I_{IR} channels were found, indicating that at least some of the apparent downregulation may be due to insertion of channels on electrotonically distant membranes.

The external signals which regulate ionic channel phenotype have also been investigated. Elevations in the intracellular cyclic AMP level is an ubiquitous trigger governing many aspects of Schwann cell differentiation (Sobues et al., 1986). Given the correlation between I_{IR} expression and differentiation it is not surprising that cAMP does have effects on Schwann cell ionic channel expression. In culture, Schwann cells from neonatal mouse lose I_{IR}, while incubation in cell permeant cAMP analogues trigger the reexpression of I_{IR} (Konishi, 1992).

Potassium Current Kinetics and Single-Channel Properties in Schwann Cells

In general, both whole-cell and unitary current properties of these K^+ currents are similar to those observed in other glial and neuronal cells. The channel that underlies the macroscopic I_{IR} of rat sciatic nerve Schwann cells was found to be quite similar to the I_{IR} in other glia, with a single-channel conductance of 35 pS (in 160 mM K^+), and showing significant $[K^+]_0$ sensitivity (Wilson and Chiu 1990a). A slightly lower gk was observed in cultured human Schwann cells (18 pS in 140 mM K^+) (McLarnon and Kim 1991) and rat Schwann cells at the paranode (25 pS) (Wilson and Chiu, 1990b). Moreover, like other I_{IR} channels opening probability increased with depolarization, reaching a maximum around E_m. The 4-AP-sensitive I_{DR} channel has a slope conductance of 12 to 14 pS (Schrager et al., 1985; Wilson and Chiu 1990a, 1990b; Howe et al., 1992), similar to the neuronal I_{DR} channel (Wilson and Chiu, 1990b), while the 4-AP-insensitive outward rectifier has a single channel conductance of around 60 pS (Howe et al., 1992).

Functions of Schwann Cell Potassium Channels

From a functional standpoint, the expression of I_{IR} may indicate that Schwann cells play some role in the buffering of interstitial K^+. The finding of I_{IR} channels opposed to paranodal regions (Wilson and Chiu, 1990b) where interstitial K^+ accumulation may be highest (Chiu, 1991), or during developmental periods where accumulation may be potentiated (Connors et al., 1983) is suggestive of such a role. Also, elevated external $[K^+]_0$ potentiated inward K^+ currents through I_{DR} (Verkhratsky et al., 1991), suggesting that these channels also may contribute to K^+ buffering. Elevations in extracellular pH, which accompany nerve activity under some conditions (Jendelova and Sykova, 1991) also potentiated inward K^+ currents (Hoppe et al., 1989). However, myelinated Schwann cells lack dye coupling (Konishi, 1990b), a possible prerequisite for significant K^+ clearance. It is also possible that Schwann cells could, in a manner analogous to that proposed for astroglial cells or oligodendrocytes, accumulate K^+ by K^+ and Cl^- influx. High-conductance anion channels (gk > 300 pS) have been measured from cultured human (McLarnon and Kim, 1991) and rabbit (Howe and Ritchie, 1988), Schwann cells and from rat spinal root Schwann cells in freshly isolated nerve (Quasthoff et al., 1992). It is clear that I_{IR} does play a dominant role in setting the resting membrane potential, since Schwann cell E_m hyperpolarizes as I_{IR} expression increases (Chiu and Wilson, 1989; Konishi, 1990b). Modulation of E_m may, in fact, be the most important role of I_{IR} channels given that E_m seems to be an important modulator of Schwann cell proliferation. Increases in I_K and hyperpolarizations of E_m following Wallerian degeneration (Chiu and Wilson, 1989) were accompanied by proliferation as indicated by increases in [^{3}H]thymidine incorporation. Significantly, K^+ channel antagonists blocked proliferation with approximately the same potency as they blocked ion channels (Chiu and Wilson, 1989; Konishi, 1989b). However, the mechanism by which low E_m induces proliferation is not clear.

POTASSIUM CHANNELS IN MICROGLIAL CELLS

Microglial cells represent the resident brain population of macrophages (see Perry and Gordon, 1988; Thomas, 1992; Benveniste, 1993; and Chapter 10, this volume for reviews of microglia origins and physiology). The question of their electrophysiological properties is of some interest because the ionic channel expression pattern of immune cells is intimately related to developmental state, and can be altered by mitogens which regulate immune cell function (Lewis and Cahalan, 1988). For example, K^+ channel activity increases during phagocytosis (Ince et al., 1988). In microglial cells cultured from rat brain Kettenmann et al. (1990) observed an inwardly rectifying current with similar single channel conductance to other glial inward rectifiers (30 pS in 150 mM K^+) but no depolarization-activated outward current (Figure 11-6). In contrast both inward and outward K^+ currents were reported in cultured microglia (Korotzer and Cotman, 1992). These authors also noted that ramified microglia were more likely to express I_{Na} than amoeboid cells, suggesting that ionic channel expression may indeed be correlated with physiological state. Again the functional role played by these channels is not clear. As pointed out in Kettenmann et al. (1990) the inward rectifier could, by maintaining the resting potential near E_K, provide an electrochemical driving force for transport. Also, inward rectification would substantially increase membrane input resistance during depolarization. This in turn would greatly amplify the effect of any depolarizing signal from Na channel opening (Korotzer and Cotman, 1992) or neurotransmitter stimulation (Kettenmann et al., 1993).

CONCLUSIONS

The predominant electrophysiological characteristic of glial cells is still the high relative K^+ permeability

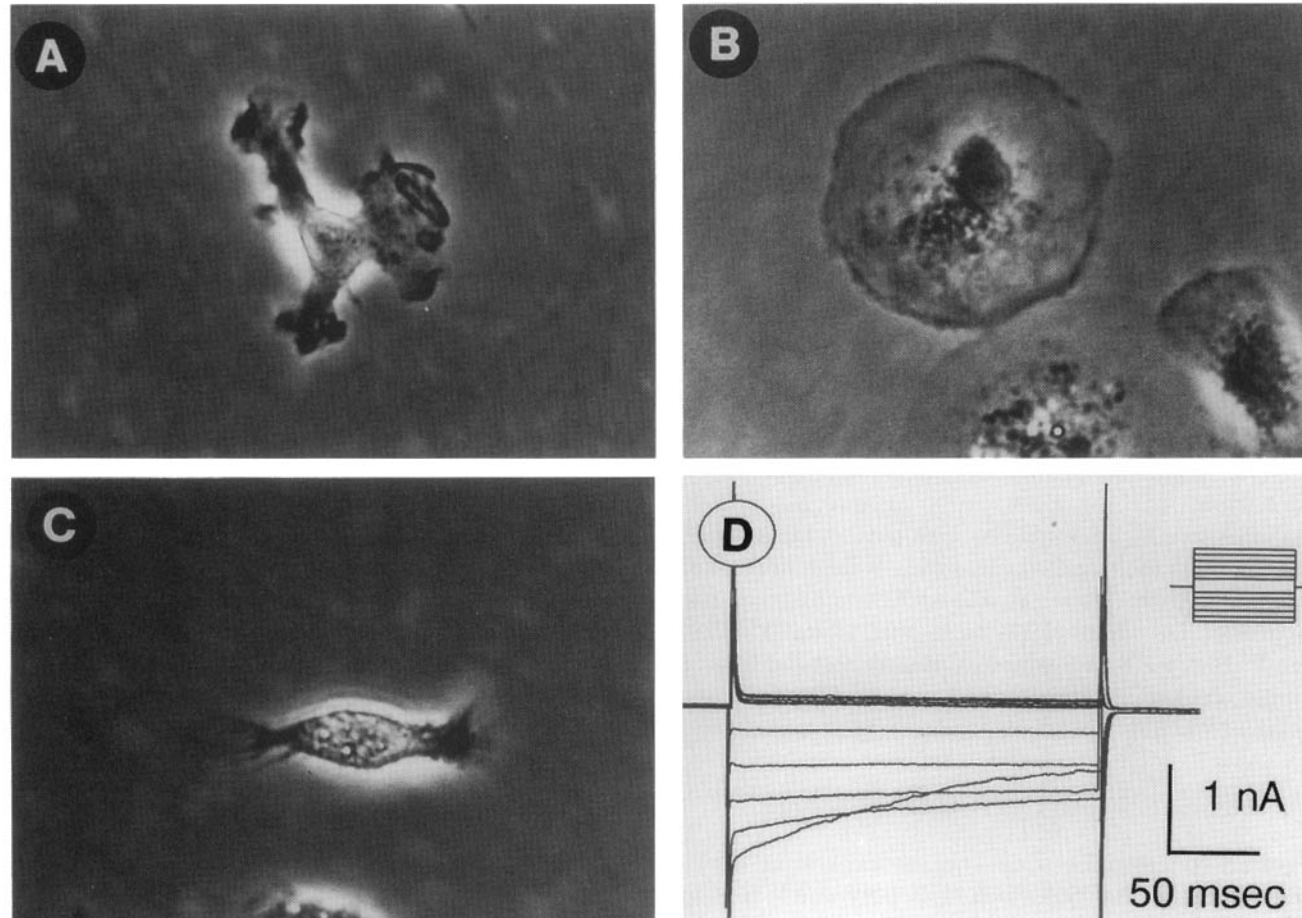

FIG. 11-6. Whole-cell voltage-clamp recordings obtained from microglial cells in cell culture. (A–C) Photomicrographs of microglial cells in a purified culture illustrating their diverse morphologies. Whole-cell voltage-clamp recordings were obtained from the displayed cells. (D) Typical pattern of membrane currents obtained from a microglial cell at a holding potential of −70 mV. Voltage-gated currents (I_{IR}) were observed only when the cell was hyperpolarized during voltage command steps of 20 mV increments. Note that I_{IR} inactivates at more hyperpolarized potentials. [From Kettenmann et al. (1990), with permission.]

of their membrane. The possibility that extracellular potassium is regulated by glial cells (as discussed in Chapter 47, this volume) is based upon our understanding of the membrane properties of these cells. The experimental work of the last few years has revealed that glial cells have many types of K^+ channels. The presence of several species of voltage gated channels suggests a dynamic nature of their K^+ permeability. A major challenge in the near future will be to synthesize the experimental observations of the diverse K^+ channels within a conceptual framework of glial function.

12 Voltage-gated sodium and calcium channels

HARALD SONTHEIMER AND J. MURDOCH RITCHIE

Little was known about the electrophysiological properties of the satellite cells of the nervous system (Schwann cells in the peripheral nervous system; astrocytes and oligodendrocytes in the central nervous system) until the seminal work of Kuffler, Nicholls, and Orkand in 1966 on the glial cells of the optic nerve of the mudpuppy, *Necturus*. They showed not only that the resting potential of these cells (about −90 mV) was determined by the K^+ gradient across the membrane, but also that during impulse activity the K^+ released by axons accumulates in the intracellular clefts, thereby reducing the glial membrane potential. This work clearly established the presence of K^+ channels in the glial cell membrane, and it set the stage for the remarkable period of frenzied discovery that was to occur in the 1980s.

The amphibian K^+ channel described by Kuffler and collaborators was "passive" in the sense that the membrane resistance did not change when the resting potential was displaced by 100 mV or more in either direction. Nor were glial cells found to generate electrical signals when the membrane was depolarized. In other words, none of the then known properties of glial cells suggested the presence of the voltage-gated channels (K^+, Na^+, Ca^{2+}) that are used by the nervous system to generate nerve impulses; and there the position rested for the next 25 years, until the advent of patch-clamp techniques allowed the extension of the earlier work on amphibian glial cells to mammalian glia.

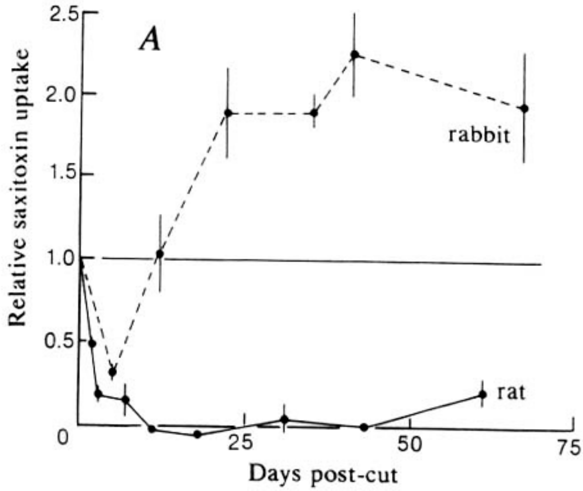
The first report of K^+ channels in mammalian oligodendrocytes appeared in 1982 (Kettenmann et al., 1982), and in 1984 a calcium-activated cation-selective channel was described in rat cultured Schwann cells that was equally permeable to Na^+ and K^+ ions but not detectably permeable to Ca^{2+} ions (Bevan et al., 1984b). Although the opening probability of the latter was somewhat affected by membrane potential neither of these two channels could strictly be called voltage-gated. However, in the decade that followed, it became clear that all the satellite cells of the nervous system (oligodendrocytes, astrocytes, Schwann cells) are liberally endowed with a large repertoire of voltage-gated ion channels. In 1984, voltage-gated Ca^{2+} channels were described in astrocytes by MacVicar (1984); and Hodgkin Huxley type K^+ and Na^+ channels were described for both Schwann cells and astrocytes (Bevan et al., 1984a; Chiu et al., 1984). Voltage-gated anion channels were described for astrocytes in 1985 (Bevan et al., 1985) and for Schwann cells in 1988 (Howe and Ritchie, 1988). The present chapter focuses on the electrophysiological properties of the satellite cell voltage-gated Na^+ channels. Ca^{2+} channels will also be discussed, but briefly because so far they have been less extensively studied.

SCHWANN CELLS

Sodium Channels in Schwann Cells

Saxitoxin Binding. The first suggestion that the satellite cells of the nervous system express neuronal-type Na^+ channels came from experiments where a highly specific marker for Na^+ channels, saxitoxin (STX), was used to follow the disappearance of axons from sectioned rat and rabbit sciatic nerves undergoing Wallerian degeneration (Ritchie and Rang, 1983). In the rat (Figure 12-1A) the uptake of [^{3}H]STX virtually completely disappeared in a few days after section, as would be expected from the subsequent degeneration and loss of axons. Completely unexpected, however, was the finding in sectioned rabbit nerve. After an initial fall the binding began to increase; and a month after nerve section, the now axon-free degenerated distal nerve stump expressed about twice as many STX-binding sites as did the control nerve.

Electrophysiological Experiments. Electrophysiological experiments rapidly showed that the STX binding indeed reflected expression of voltage-gated Na^+ channels in Schwann cells (Chiu et al., 1984; Shrager et al., 1985; Howe and Ritchie, 1990). Figure 12-1B shows a typical whole-cell patch-clamp recording from a rabbit Schwann cell. As can be seen from the corresponding current-voltage plot (Figure 12-1C)



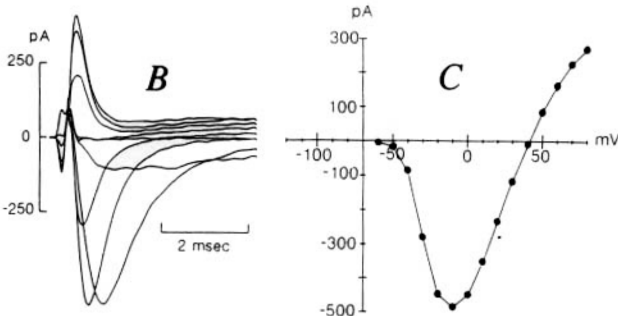


FIG. 12-1. Na^+ channels in Schwann cells. (A) Binding of [^{3}H]STX to desheathed rat and rabbit sciatic nerves after nerve section. The uptakes in the cut nerves are expressed as fractions of the uptake in control contralateral nerves. (B) Family of Na^+ currents recorded from rabbit cultured Schwann cell evoked by 10 mV depolarizing voltage steps (every second shown) to test potentials of −60 to +100mV. (C) Current-voltage curve obtained from the records shown in Figure A. [Figure A: from Ritchie and Rang (1983), with permission; Figures B and C: from Howe and Ritchie (1990, 1992), with permission.]

the current, which is initially inward, becomes outward at potentials more positive than about +40 mV. This reversal potential corresponds closely with the equilibrium potential for Na^+ calculated from the Na^+ concentrations in the extracellular and pipette solutions. As with axonal sodium channels, the Schwann cell Na^+ channel is blocked in a 1:1 manner by low concentrations of STX, the equilibrium dissociation constant for block being about 2 nM. Parallel STX-binding experiments give a similar value for the equilibrium dissociation constant of binding. Fibroblasts (the other major component of the degenerated nerve trunks of Figure 12-1A) express neither inward currents on depolarization nor do they bind STX. Contrary to the conclusion originally drawn from the experiment of Figure 12-1A, rat cultured Schwann cells do indeed bind STX and express Na^+ currents and STX-binding. However, such expression is very small (on average about 7% of the corresponding values in the rabbit), which probably accounts for it being missed originally.

Sodium Channel Inactivation. It is characteristic of the Na^+ channels that underlie excitability in nerve and muscle that once activated they rapidly inactivate. Indeed, Na^+ channels in such excitable tissue display multiple components of inactivation, that can be distinguished by their different kinetics with inactivation time constants ranging from fractions of a millisecond to many seconds (Howe and Ritchie, 1992, for references). As in the axon, Na^+ channels in Schwann cells can also exist in at least three different inactivated states.

The first two components of inactivation in Schwann cell Na^+ channels are fast; and steady-state inactivation is well described by an h_∞ curve that is quite similar to that of the associated myelinated axon (Chiu et al., 1979). The Hodgkin-Huxley equations predict a single exponential decay of the Na^+ current. However, as Chiu (1977) has shown, this decay in myelinated nerve is in fact biexponential. The onset of inactivation in Schwann cell Na^+ channels is similarly biexponential. Thus the decay of Na^+ current is best fitted by two exponential components (I_{h1} and I_{h2}), one with a time constant (τ_{h1}) of about 0.5 ms and a second with a time constant (τ_{h2}) about five times as large. Although the amplitude of the slower h_2 component is quite small (about 5% of the total) it is consistently found (Howe and Ritchie, 1992). In addition, there is a third inactivated state (I_{hs}) into which the channels enter very slowly on depolarization with a time constant (τ_s) of several seconds.

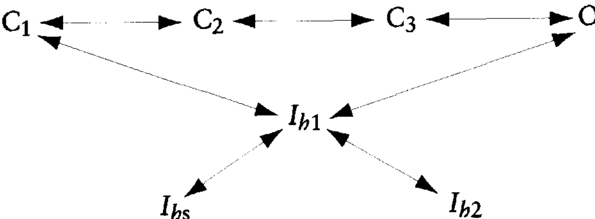
Recovery from this latter inactivated state, though faster than its onset, is still slow, the time constant at −120 mV being 1.2 to 1.5 seconds. Table 12-1 shows the value for the onset and offset time constants as well as the steady-state value of the ampli-

TABLE 12-1. *Schwann Cell Inactivation Time Constants*

	Onset (fast)		Onset (slow)	Offset (slow)	
Potential (mV)	τ_{h1} (msec)	τ_{h2} (msec)	τ_{hs} (msec)		A_s (%)
0	0.47	2.7	6580	1200	0.80
−20	1.11	5.8	–	–	–
−50	(5.0)	—	6980	1160	0.56
−70	—	—	6980	1480	0.36

Mean time constants for the onset of fast (τ_{h1}, τ_{h2}) and slow (τ_{hs}) inactivation at membrane potentials of 0, −20, −50 and −70 mV and for the recovery (at −120 mV) from slow inactivation at holding potentials of 0, −50 and −70 mV. A_s gives the fraction of the channels that are in the slow inactivated state at these potentials. (From Howe and Ritchie, 1992).

tude of this slow component (A_s). Interestingly, at −70 mV (the potential at which Schwann cells are often held in patch-clamp experiments) nearly 40% of the channels are in this slow inactivated state and would not be recruited by the usual brief (100 ms) prepulse to −120 mV before a test pulse. Based on these and other experiments the following model has been proposed for the balance between the closed (C), open (O), and inactivated (I_{h1}, I_{h2}, I_{hs}) states (Howe and Ritchie, 1992).



These results indicate that Na^+ channels in Schwann cells can exist in at least three different inactivated states; and they provide further evidence for the similarity between satellite cell Na^+ channels and the Na^+ channels in their associated axons. Whether yet other inactivated states, with inactivation time constants of minutes also exist in Schwann cells as they do in myelinated nerve and muscle (Fox, 1976; Almers et al., 1983) has not been determined; but such states might account for some of the unavailability of Na^+ channels in electrophysiological experiments.

Although the amplitude of the second fast-inactivating component I_{h2} is normally relatively small, its amplitude relative to that of the I_{h1} component is greatly increased in the decay of sodium currents recorded from cells exposed to internal iodate or to venom from the scorpion *Leiurus* (Howe and Ritchie, 1992). These agents not only alter the relative amplitudes of the two components but also increase τ_{h1} and τ_{h2}. Again, these findings are similar to those found in axonal Na^+ channels (Schmidtmayer, 1985; Neumcke et al., 1987).

Sodium Channel Turnover in Schwann Cells. One speculation for the function of Schwann cell Na^+ channels (see below) is that in the intact animal they are indeed expressed in Schwann cells (where they have no direct function), but are ultimately transferred to (and used by) the axolemma (Gray and Ritchie, 1985; Shrager et al., 1985). The need for such a supplementary mechanism might be particularly acute if the turnover of the channels in the membrane were fast.

An estimate of the lifetime of the sodium channels can be obtained by exposing Schwann cells in culture either to proteolytic enzymes (such as Dispase-collagenase) or to inhibitors of glycosylation (Ritchie, 1988). The former destroys STX-binding capacity, which gradually reappears with an exponential time constant of about 3.1 days; exposure to the latter leads to a progressive exponential fall in STX-binding capacity—again with a time constant of about 3.1 days (Figure 12-2). The assumption that the steady-state density of Schwann cell Na^+ channels is maintained by a constant synthesis of channels in the face of a rate of loss from the membrane proportional to the amount of channel already present leads to the conclusion that these channels have an average lifetime of about 3.1 days, which corresponds with the half-life of 2.1 days. This time is the same order of size as the value of 26 hours for the half-life of Na^+ channels in neuroblastoma cells (Waechter et al., 1983) and value

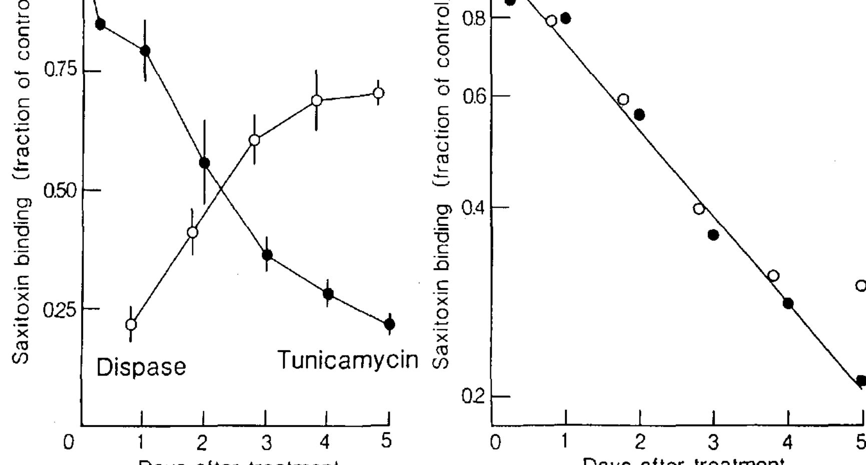


FIG. 12-2. (A) Sodium channel lifetime. The uptake of [^{3}H]STX by rabbit-cultured Schwann cells following exposure either to proteolytic enzymes (dispase-collagenase) (*open circles*) or to tunicamycin (*filled circles*). (B) Same data as in Figure A plotted semilogarhythmically. [From Ritchie (1988), with permission.]

of 2 days found by Schmidt and Catterall (1986) for Na^+ channels in cultured rat neurons. Clearly, a rapid turnover would impose a large metabolic load on the neuron if all the channels in the axon had to be made in the cell body. It has been calculated, for example, that the smallest neuron in the central nervous system might be required to replace as much as 8% of its total protein mass as sodium channels daily (Ritchie, 1988); this replacement would seemingly present a not inconsiderable metabolic load, which would be even greater in remyelinating and regenerating remyelinating nerve where there are many more nodes per unit length of nerve.

Cytoplasmic Sodium Channels. The STX-binding experiments (see Figure 12-1A) indicate that there are about 80,000 binding sites per cell (Howe and Ritchie, 1990). However, even with the maximum sodium current then recorded in Schwann cells (1.2 nA) Shrager et al. (1985) estimated that each cell contained only about 1000 functional sodium channels, which is very much less than the number of binding sites. However, this estimate (based on the ratio of the peak whole-cell and single channel conductances) implicitly assumes that all the channels are open simultaneously at the peak of the Na^+ current, which may not be the case (Aldrich et al., 1983). A more general approach is to estimate the number of channels by dividing the *charge* carried by the whole-cell current, that is, the time-integral of the current, during a depolarizing epoch by the charge carried by a single channel during a similar depolarizing epoch. On that basis the estimate of the number of electrophysiological Na^+ channels becomes nearly 14,000 per cell (Ritchie, 1986), which is still below that estimated from STX-binding. One factor that contributes to the remaining apparent discrepancy is that Schwann cells have long, narrow processes, which must be largely ignored by the recording system in voltage-clamp experiments and so would not contribute to the peak current recorded. For example, in addition to the capacitance associated with the cell soma there is an additional, almost as large, "slow" capacitance, which, because of its high access resistance, is not properly voltage-clamped (Howe and Ritchie, 1992). A second factor is that the Schwann cells are usually held at −70 mV for patch-clamping so that 40% of the channels, being in the long-lasting inactivated state, cannot contribute to the current. Finally, a good deal of the STX binding may well be to *intra*cellular Na^+ channels that have been synthesized by the Schwann cell but have not yet been inserted into the membrane. Lysing of the cells during the binding experiment (by the centrifugation, for example) would expose these channels. The extent to which this factor might contribute can be readily assessed by comparing the [^{3}H]STX binding in Schwann cells both intact and after homogenization. These experiments show that there are indeed approximately equal pools of plasmalemmal and cytoplasmic STX-binding sites (Ritchie et al., 1990). These various factors taken together bring the two estimates, from electrophysiological and STX-binding experiments, reasonably close together.

Current-Voltage Curves. The current-voltage (*I-V*) curve for rabbit Schwann cells (Figure 12-1C), indicates a peak inward current at about −5 mV; and it reverses near a calculated E_{Na}. While this curve is generally similar in shape to that found in rabbit and rat sciatic axons it is clear that the Schwann cell *I-V* curve is shifted along the voltage axis by about 25 mV in the depolarizing direction relative to the curves obtained from the mammalian nodes of Ranvier. In optic nerve astrocytes (see later) the *I-V* curve is also shifted relative to the neuron it invests (the retinal ganglion cell) but in the *opposite* direction; this shift has been interpreted as reflecting the presence of two sodium channels with two quite different molecular structures (Barres et al., 1989b). While such isoforms of the sodium channels are possible (even likely) it seems dangerous to use a shift along the voltage axis as evidence since such a shift could readily be produced by changes in the fixed charges on the inner or outer plasmalemmal surfaces of different cell types or even of the same cell type at different stages of development. Furthermore, large shifts in the *I-V* curve along the voltage axis are readily produced by drugs (such as iodate or scorpion toxins) that acutely modify Na^+ channel activation and inactivation; such shifts occur too quickly for changes in the molecular structure to happen (Cahalan, 1975; Howe and Ritchie, 1992). Even the act of patching produces a substantial shift in the hyperpolarizing direction (Howe and Ritchie, 1992). It is interesting that in the hippocampus the astrocytic and neuronal *I-V* curves follow the pattern of the Schwann cell and its axon rather than the pattern in the optic nerve insofar as the astrocytic *I-V* curve is shifted in the depolarizing direction relative to its neuron (Sontheimer et al., 1991b).

Are Schwann Cell Sodium Channels Normally Expressed? It has been suggested (Chiu, 1987, 1988) that adult Schwann cells that are attached to myelinated fibers do not normally express voltage-gated Na^+ channels, whereas nonmyelinating Schwann cells do. It has further been suggested that this differential expression of sodium channels (i.e., in myelinating as compared with nonmyelinating Schwann cells) may

be absent in newborn animals, thus accounting for the finding that all Schwann cells cultured from neonatal sciatic nerves yield a Na^+ current (Chiu, 1987, 1988). However, no substantial differences have been noted either in the passive electrical properties (input resistance, cell capacitance, resting membrane potential) or in the active electrophysiological properties (peak Na^+ current, membrane potential, *I-V* curve, h_∞) of the whole-cell or single-channel Na^+ currents in Schwann cells from both sciatic and vagus nerves obtained from both neonatal and adult rabbits (Howe and Ritchie, 1990); in the adult these nerves are predominantly myelinated and nonmyelinated, respectively. On this basis the conclusion has been drawn that the expression of Na^+ channels in myelinating Schwann cells does not differ substantially from that of nonmyelinating Schwann cells, nor does it depend on the state of development. The explanation for the reported inability to record Na^+ currents from freshly dissociated myelinating Schwann cells with the patch-clamp method in the whole-cell mode (Chiu, 1987, 1988) seems to be a consequence of the high input capacitance (reported to be on average 670 pF) in conjunction with a series resistance of 10–20 MΩ (see Howe and Ritchie, 1990).

Arguing against Na^+ channels being present normally is the inability to find Na^+ channels in *patches* formed from rabbit sciatic nerve soon after dissociation (Wilson and Chiu, 1990). However, Na^+ channels in patches are known to be elusive. For example, Barres et al. (1989b) found in type 1 astrocytes that although large inward currents were observed in whole-cell recording, such channels were rarely found in patches formed on the soma. Furthermore, the way cells are prepared is important. For example, the usual acute dissociation procedure virtually abolishes the expression of Na^+ currents in Schwann cells (Ritchie, 1988). After a similar procedure in astrocytes only 10 to 20% of them express Na^+ currents, whereas *all* do so if isolated by a less severe procedure of "tissue printing" (Barres et al., 1990a).

Sodium Channels Are Expressed by Schwann Cells In Vivo. The original STX-binding experiments (Figure 12-1A) showed that Na^+ channels were clearly expressed by Schwann cells *in vivo* in the pathophysiological situation of Wallerian degeneration. Two lines of evidence indicate the presence of Na^+ channels in normal nerve *in vivo*. Ritchie and Rogart (1977) found that the total amount of STX bound to intact rabbit sciatic nerve was about 20 fmole mg^{-1} wet nerve. They estimated (from binding experiments to the nonmyelinated vagus nerve) that the sciatic nonmyelinated fibers (and their associated Schwann cells) bound less than 3 fmole mg^{-1} wet nerve. With an internodal axolemmal density of 25 μm^{-2} and an average nodal density of at most 2000 μm^{-2} (as suggested by electrophysiological experiments), only about 10 fmole mg^{-1} could be bound to axolemma (nodal and internodal) meaning that about half the total binding must have been to Schwann cells (Howe and Ritchie, 1990). Furthermore, these must have been myelinating Schwann cells because binding to the nonmyelinated fibers and their Schwann cells was already included in the 3 fmole mg^{-1} "nonmyelinated" estimate given above.

But perhaps the strongest evidence in favor of *in vivo* expression of sodium channels by myelinating Schwann cells comes from immunoblotting experiments with a polyclonal antibody, 7493, that is directed against purified Na^+ channels from rat brain and which specifically recognizes a 260 kD protein corresponding to the alpha subunit of the Na^+ channel (Ritchie et al., 1990). Sections through both the internodal and perinodal regions of the Schwann cell in rat sciatic nerve clearly show the presence of Na^+ channels (Figures 12-3A, B).

Calcium Channels in Schwann Cells

Ca^{2+} currents have not been observed in cultured Schwann cells from rabbit or rat sciatic nerve, the two preparations that yielded invaluable data on the expression of Na^+ channel in Schwann cells (see above). However, a recent study of "organotypic" cultures from mouse dorsal root ganglia shows the expression of whole-cell Ca^{2+} currents by Schwann cells (Amedee et al., 1991). In this study, both L- and T-type Ca^{2+} channels could be identified pharmacologically and kinetically. Interestingly, channels were only expressed when dorsal root ganglion neurons were present in the culture, suggesting that, in culture, neurons may induce the expression of Schwann cell Ca^{2+} channels as previously also shown for cultured rat cerebral astrocytes (Corvalan et al., 1990).

ASTROCYTES

Three major types of glia exist in the central nervous system: oligodendrocytes and two kinds of astrocytes. Only the latter express Ca^{2+} and Na^+ channels, and their expression depends on various factors, including the subtype of astrocyte, which part of the brain it is from, its association with neurons,

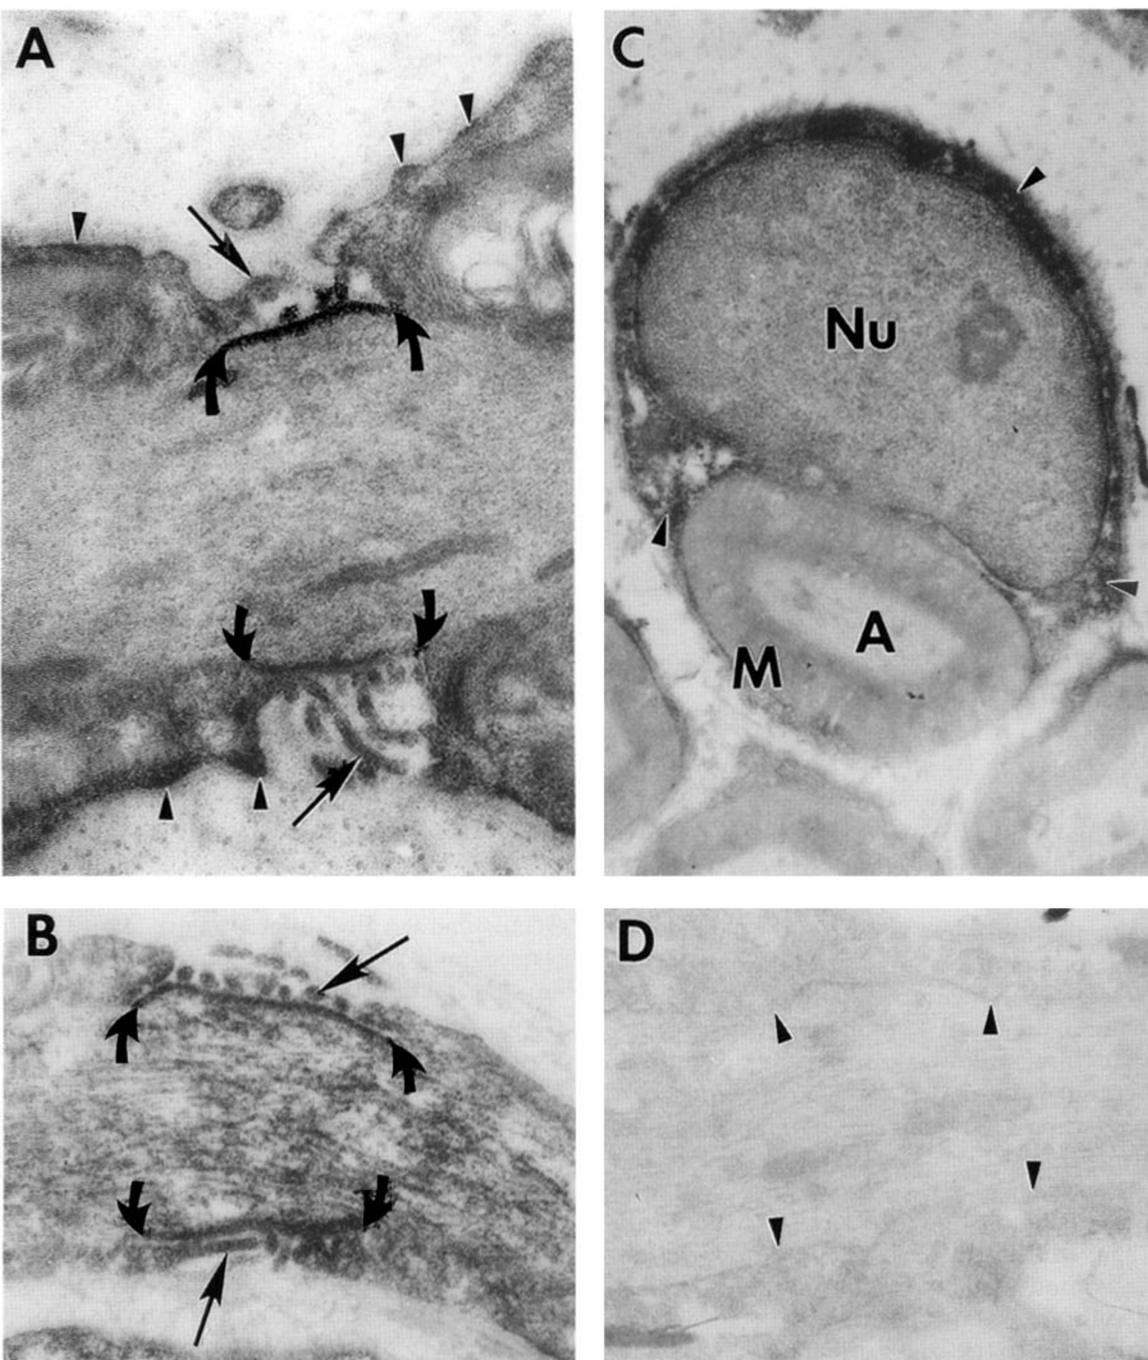

FIG. 12-3. Antibody 7493 immunostaining in Schwann cells of adult sciatic nerve. Nodal axon membrane (*between curved arrows*) of thickly (A) and thinly (B) myelinated nerve fibers display sodium channel immunoreactivity. Perinodal processes (*arrows*) and outer cytoplasmic compartments (*arrowheads*) of Schwann cells exhibit immunostaining. The immunoreactivities are associated both with the cytoplasm and with the Schwann cell plasmalemma. Note the lack of 7493 immunoreactivity in the myelin sheath (*M*) and the paranodal axon membrane. (C) Cytoplasma of myelinating Schwann cell. Note that the Schwann cell nucleus, *Nu*, but not the myelin sheath (*M*) nor the axon (A) display sodium channel immunostaining. (D) Sections incubated with preimmune serum show complete lack of immunoreactivity of nodal axon membrane and Schwann cell processes. (E) 7493 immunoreactivity at node of Ranvier in perinodal astrocyte in rat optic nerve. The axon membrane and subjacent axoplasma at the nodes of Ranvier (*between arrowheads*) exhibits intense immunostaining. Perinodal astrocyte processes (As) are densely immunostained. Note that axon membrane beneath paranodal loops (*PN*) is not immunoreactive. [Figures A–D: from Ritchie et al. (1990), with permission; Figure E from Black et al. (1989), with permission.] *Figure continues*

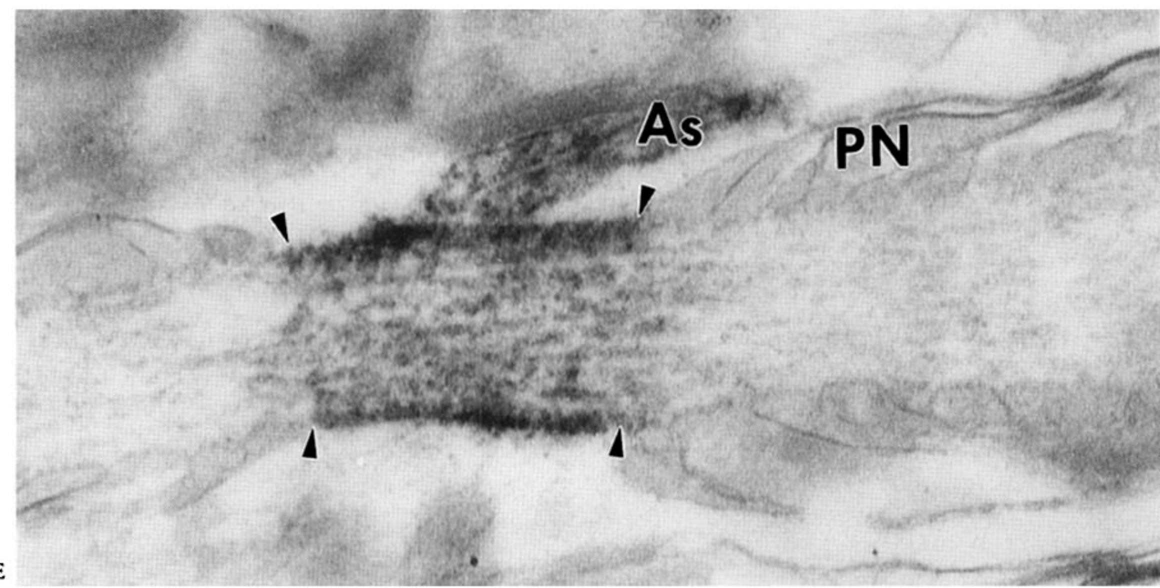

FIG. 12-3. *Continued*

and its developmental stage. These factors will be considered in detail below.

Astrocyte Subtypes

Ramón y Cajal (1913) showed that there are two distinct morphological types of astrocytes in the brain which he termed "protoplasmic" and "fibrous." In intact brain, the fibroblast-like protoplasmic astrocytes are the predominant astrocytes in gray matter, whereas the process-bearing stellate astrocytes resemble white matter astrocytes. These two subtypes of astrocytes are typically represented in cultures from gray and white matter brain areas; and both subtypes often coexist on the same culture. This lineage of astrocytes has been extensively studied in cultures of rat optic nerve, where the two astrocyte subtypes can be further distinguished antigenically (Raff et al., 1983a; Miller and Raff, 1984). Only process-bearing cells bind the monoclonal antibody A2B5; but both subtypes stain positive with astrocyte-specific antibodies to the glial fibrillary acidic protein (GFAP) (Eng, 1985). Interestingly, the two types of rat optic nerve astrocyte develop from different precursor cells; and fibrous astrocytes share a common precursor cell with oligodendrocytes. For simplicity, the two rat optic nerve types were termed type-1 astrocytes ($GFAP^+/A2B5^-$; flat, fibroblast-like) and type-2 astrocytes ($GFAP^+/A2B5^+$; stellate, process-bearing) (Raff et al., 1983a); and this nomenclature has been widely adopted to classify morphologically distinct types of astrocytes regardless of cell origin. Although astrocyte types, distinguished by selective binding of A2B5 antibodies, were subsequently found in rat cerebellar (Levi et al., 1986) and cortical (Levi et al., 1986) cultures, the use of A2B5 antibody for astrocyte classification is not always possible. For example, in rat hippocampal cultures (Sontheimer et al., 1991b), where astrocytes of both morphologies exist, all astrocytes lack A2B5 binding; and in rat spinal cord cultures, where an even greater number of morphologically different types exist, the astrocytes cannot be subdivided on the basis of A2B5 staining (Miller and Szigeti, 1991; Black et al., 1993). Furthermore, A2B5 antibody staining fails to label astrocytes selectively *in vivo* (Miller et al., 1989).

As a result of this heterogeneity of astrocytes, the terms type-1-like and type-2-like astrocytes are frequently used in the literature, referring mostly to morphologically identified astrocytes that comply with the morphological criteria defining protoplasmic (i.e., flat, fibroblast-like) and fibrous (i.e., stellate, process-bearing). Since the terms type-1 and type-2 were introduced for rat optic nerve astrocytes, which are characterized not only by differences in A2B5 binding but also by specific lineage relationships (Raff et al., 1983a, 1983b; Temple and Raff 1985), this terminology is not always applicable and should be used only for rat optic nerve astrocytes. For simplicity, in the following discussion all astrocyte types will be referred to as protoplasmic or as fibrous, emphasizing only their morphological difference without implying different regional origins (e.g., white or gray matter) or unique lineage.

Calcium Channels in Astrocytes

Although voltage-gated Ca^{2+} channels were among the first to be described (MacVicar, 1984) they have been less extensively studied. They are, however, clearly present in astrocytes. Under conditions where Na^+ and K^+ channels are blocked, and where Ca^{2+} ions are replaced by Ba^{2+} ions (which pass more easily through Ca^{2+} channels) action potentials can be evoked by electrical stimulation of cultured rat astrocytes; and they can even occur spontaneously (Figure 12-4A). The Ca^{2+} current depends markedly on prior exposure of the astrocytes to agents that raise the intracellular concentration of cAMP, such as dibutyryl cAMP (dcAMP), norepinephrine, and isoproteranol (MacVicar and Tse, 1988), as well as 8-bromo-cAMP, forskolin, and vasoactive intestinal peptide (Barres et al. 1989a). This current is mostly an L-type Ca^{2+} current (as defined in McCleskey et al., 1986), and is blocked by nifedipine, Co^{2+}, and Cd^{2+}. Relative to the other glial cell currents, the Ca^{2+} current is relatively small (25 to 200 pA) being 1 to 2 orders of magnitude smaller than Na^+ or K^+ currents.

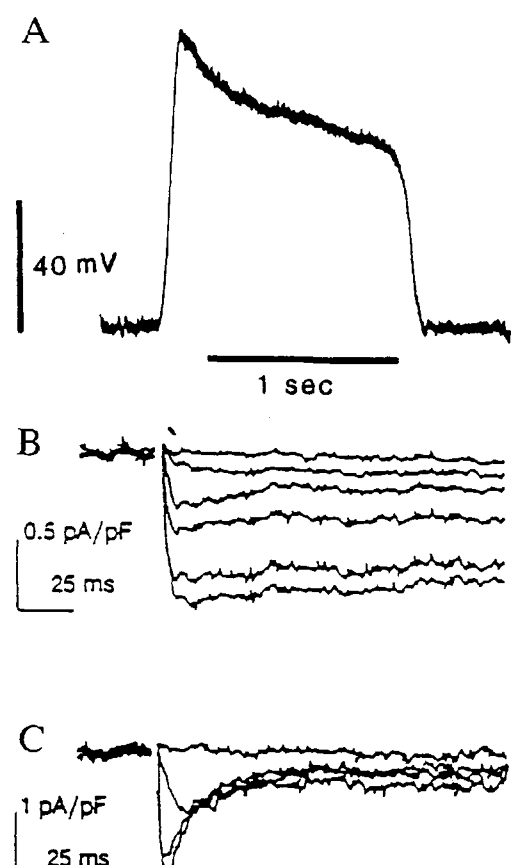

FIG. 12-4. (A) Spontaneous Ca^{2+} action potential in rat astrocyte (in Ba^{2+} Locke solution). [From MacVicar (1984), with permission.] (B, C) L-type and T-type Ca^{2+} currents in type-1 rat optic nerve astrocytes in response to families of depolarizing steps between −60 and +25 mV, and −60 and −5 mV, respectively. [From Barres et al. (1990), with permission.]

Astrocytes in culture, however, usually do not express Ca^{2+} currents. Indeed, MacVicar's original demonstration of astrocytic Ca^{2+} currents probably owed its success to the fact that the cortical astrocytes being studied had been "rounded" by a 2-hour exposure to dcAMP some hours beforehand to facilitate recording. However, factors other than the drug-induced action described above may also be involved. For example, forskolin does not always induce astrocytic Ca^{2+} currents—only in the presence of a few batches (less than 20% of number tested) of the fetal calf serum used in culturing (Barres et al., 1989a). Furthermore, while the Ca^{2+} current is L-type when induced by some lots of serum, with other lots the current is of the more transient T-type. The former activates at −30 mV and inactivates quite slowly, whereas the T-type current activates at about −60 mV and has a rapid voltage-dependent inactivation.

One of the most intriguing findings is that the expression of Ca^{2+} currents by glial cells critically depends on the presence of neurons. Thus, Corvalan et al. (1990) have shown that, whereas no inward currents can normally be detected in pure cultures of rat cortical astrocytes, both L-type and T-type Ca^{2+} currents are expressed when the astrocytes are cocultured with neurons. This dependence on neuronal presence is reminiscent of the similar dependence of Na^+ currents described later for rat optic nerve astrocytes (Figure 12-6).

The method of cell isolation also seems to be important. Thus, although Ca^{2+} currents are normally absent in cultured type-1 rat optic nerve astrocytes, both types of Ca^{2+} current are detected when the astrocytes are acutely dissociated from freshly excised nerve by the new "tissue print" procedure involving treatment with the proteolytic enzyme papain (Barres et al., 1990a). Some cells express just L-type currents (Figure 12-4B), others just T-type currents (Figure 12-4C), while others express both. Even with the tissue print procedure, however, astrocytes prepared from transected (i.e., axon-free) optic nerve do not express Ca^{2+} currents—which might be explained by the neuron-glial interaction just described.

Sodium Channels in Astrocytes

Patch-clamp studies of astrocytes cultured from numerous central nervous system regions [cerebrum

(Bevan et al., 1985; Bevan et al., 1987; Nowak et al., 1987); spinal cord (Sontheimer et al., 1992a; Sontheimer and Waxman, 1992b); optic nerve (Barres et al., 1988, 1989b, 1990a; Sontheimer et al., 1991a); and hippocampus (Sontheimer et al., 1991b)] demonstrate that at least 30% of cultured astrocytes in any given cell preparation express voltage-gated Na^+ currents. These astrocyte Na^+ currents appear to be generally similar to Na^+ currents in neurons with respect to their strong voltage-dependence, rapid channel kinetics (Figure 12-5A), and the blocking action of TTX. Single-channel recordings from cultured rat optic nerve astrocytes show a single-channel conductance of 18 pS (Barres et al., 1990a), which is similar to the conductance of Na^+ channels of excitable cells (Hille, 1992).

A more detailed analysis of astrocyte Na^+ current demonstrates that the two subtypes of astrocyte (protoplasmic and fibrous) express Na^+ currents, which differ from each other in various aspects of their steady-state voltage-dependence, their kinetics, and their channel pharmacology (Figure 12-5). Thus, in astrocytes from rat optic nerve (Barres et al., 1989b; Sontheimer et al., 1991a), hippocampus (Sontheimer et al., 1991b) and spinal cord (Sontheimer et al., 1992; Sontheimer and Waxman, 1992b), two kinds of Na^+ current can be distinguished in terms of their different steady-state inactivation (h_∞) and *I-V* curves (Barres et al., 1989b; Sontheimer et al., 1991a, 1991b, 1992; Minturn et al., 1992; Sontheimer and Waxman, 1992b)). In spinal cord astrocytes, for example (Figure 12-5B), the *I-V* curves for

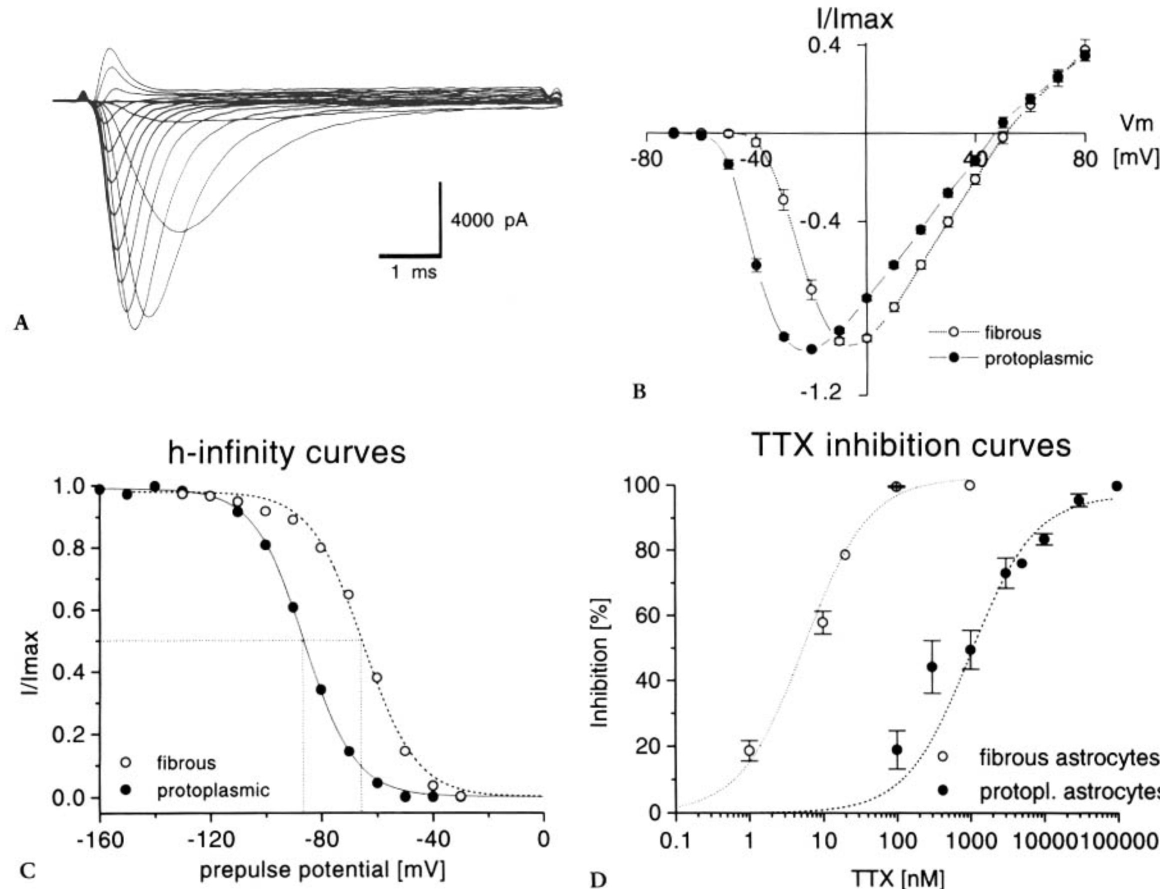

FIG. 12-5. Astrocytes subtypes express Na^+ currents with differing TTX sensitivity, activation and inactivation curves. (A) Na^+ currents expressed by astrocytes are fast, transient currents. Time to peak at 20°C is <800 μs, and current kinetics show overall resemblance of Na^+ currents in excitable cells. (B) Na^+ currents recorded in stellate and protoplasmic, spinal cord astrocytes differ in their *I-V* curves, in that the peak and activation threshold of the *I-V* curve is 16 mV more positive in fibrous cells than in protoplasmic cells. (C) Steady-state current inactivation differs similarly and shows a 20-mV positive shift fibrous astrocytes. Data in Figures C and D were normalized means from at least 20 recordings each, and the data were fit to Boltzmann equations. (D) The two astrocyte subtypes differ in their sensitivity to TTX. Na^+ currents in fibrous astrocytes are highly TTX-sensitive (K_d = 5.7 nM) whereas protoplasmic astrocytes are comparatively TTX-resistant (K_d = 1000 nM). Data displayed was obtained from 39 cells and means were fit to Langmuir binding isotherms (*dotted and dashed line*). [From Sontheimer et al. (1992a) and Sontheimer and Waxman (1992), with permission.]

fibrous astrocytes are shifted along the voltage axis in the depolarizing direction relative to those of protoplasmic astrocytes; and their activation curves are similarly shifted (on average by about 16 mV). The two astrocyte subtypes also differ in their steady-state inactivation (h_∞) curves; thus the midpoint of the curve for fibrous cells is at about -65 mV, whereas for protoplasmic astrocytes it is close to -90 mV (Figure 12-5C).

The response to TTX further emphasizes this apparent dissimilarity of Na^+ currents in the two astrocyte subtypes. Thus, as Bevan et al. (1985) first noted, Na^+ currents in rat cerebral astrocytes are relatively insensitive to TTX, micromolar concentrations being required for channel block; and similar comparatively low TTX sensitivity for Na^+ channels exists in cultured mouse cerebral astrocytes (Nowak et al., 1987).

However, this relative insensitivity to TTX applies only to protoplasmic astrocytes. Fibrous astrocytes express channels that are blocked by *nano*molar concentrations of TTX, as in neuronal and Schwann cells channels. Thus, in the spinal cord where fibrous and protoplasmic astrocytes are both expressed, both kinds of Na^+ channel, TTX-sensitive (TTX-S) and TTX-resistant (TTX-R) Na^+ channels, respectively are found. Each channel type is associated with its own morphological astrocyte type, TTX-R with protoplasmic, and TTX-S with fibrous astrocytes (Figure 12-5D). For complete block, TTX-R Na^+ channels require micromolar TTX concentrations (K_D = 1000 nM), whereas TTX-S channels require nanomolar concentration (K_D = 6 nM). Thus, in addition to differences in steady-state activation and inactivation parameters, the two astrocyte types also differ in their Na^+ channel pharmacology. Whether these differences also imply differences in the Na^+ channel protein expressed remains to be shown.

It should be noted that, although the electrical activity of rat cerebral astrocytes is relatively insensitive to TTX, these cells also express a high-affinity site (K_D ~ 2 nM) for saxitoxin, which is a specific marker for Na^+ channels (Bevan et al., 1985). One explanation would be that both TTX-R and TTX-S Na^+ channels are present in the astrocyte population, the latter being expressed, however, to a relatively small extent.

Based on differences on the voltage dependence of activation and inactivation, it has been postulated (Barres et al., 1989b) that protoplasmic rat optic nerve astrocytes (type-1) express a unique "glial" molecular form of Na^+ channel, whereas fibrous rat optic nerve astrocytes (type-2) express a "neuronal" type. However, as discussed earlier in conjunction with a similar phenomenon in Schwann cells, these steady-state parameters are influenced by numerous factors, including surface charge and toxins, so caution should be exercised in the use of such parameters for distinction. A more reliable indication that multiple isoforms of the Na^+ channel are present comes from the widely different sensitivities of fibrous and protoplasmic astrocytes to TTX. Sensitivity to TTX appears to be determined by the primary amino acid sequence of the channel protein itself (Noda et al., 1989; Yang et al., 1992). Thus, the observed difference in TTX pharmacology between the two astrocyte subtypes is more compelling in suggesting that protoplasmic astrocytes do indeed express distinct Na^+ channel proteins.

A partial clone of a putative glial Na^+ channel gene (Na-G) has recently been characterized, and the amino acid sequence deduced from this cDNA indicates that this glial Na^+ channel represents a separate molecular class within the mammalian Na^+ channel multigene family (Gautron et al., 1992), supporting the notion that a distinct astrocytic Na^+ channel exists. Nevertheless, molecular cloning, and subsequent *in vitro* expression and functional characterization of an astrocytic Na^+ channel gene is required to provide unequivocal proof.

Regional and Developmental Heterogeneity in Astrocyte Na^+ Channel Expression. In reviewing the literature of Na^+ channel expression in astrocytes, (predominantly originating from four laboratories) one is astonished at the diversity of conditions used to obtain *in vitro* preparations for study. These differences include the use of two rodent species (mouse and rat), four different brain regions (cortex, hippocampus, optic nerve, spinal cord), and numerous differences in the culture substrates and media used to maintain the astrocytes *in vitro*. Additionally, and seemingly most importantly, the time *in vitro* after which recordings were obtained and the age of culture derivation varied. Those differences are likely responsible for the apparent heterogeneity reported.

Regional Heterogeneity and Subtype Heterogeneity. In most culture preparations only subpopulations of astrocytes (typically, approximately 30% of cells) express voltage-activated Na^+ channels (Nowak et al., 1987; Sontheimer et al., 1991a, 1991b). This is also true for astrocytes that are antigenically and morphologically identical. Thus only 30 to 40% of protoplasmic (type 1) rat optic nerve astrocytes show measurable Na^+ currents at 14 to 20 DIV (Sontheimer et al., 1991a). Similarly, less than 30% of hippocampal astrocytes show Na^+ current expression after 10 to 20 DIV (Sontheimer et al., 1991b). Although in rat optic nerve and spinal cord the two morphological subtypes of astrocytes each express

its specific Na^+ current type as discussed above (Barres et al., 1989b; Sontheimer et al., 1991a, 1992b; Minturn et al., 1992; Sontheimer and Waxman, 1992b), both protoplasmic and fibrous astrocytes express identical Na^+ current types in hippocampal cultures; but the type of Na^+ current changes during *in vitro* (Sontheimer et al., 1991a) and *in vivo* (Sontheimer et al., 1992b) development.

Developmental Heterogeneity. In rat optic nerve, hippocampus and spinal cord astrocytes, Na^+ channel expression changes during *in vitro* development, and depends critically on the age of culture derivation. In contrast, cultures obtained from neonatal rat optic nerve, contain almost exclusively protoplasmic astrocytes (Raff et al., 1983a; Sontheimer et al., 1992a). Rat optic nerve astrocyte cultures obtained from P7 animals contain both morphological subtypes of astrocytes because fibrous (type-2) astrocytes develop in addition in the second postnatal week (Raff et al., 1983a, 1983b). Recordings obtained from these preparations are quite different from each other: Protoplasmic (type-1) rat optic nerve astrocytes from PO animals do not express Na^+ channels until 5 DIV (Sontheimer et al., 1991a); and, interestingly, astrocytes derived from P7 rat optic nerve show their highest level of Na^+ channel expression immediately after plating and decline thereafter. Na^+ currents are virtually absent in cells cultured for more than 14 DIV; and they are not detectable at all in cultures of adult rat optic nerve (H. Sontheimer, unpublished observations). In contrast, fibrous rat optic nerve astrocytes in the same cultures always show constant levels of Na^+ channel expression regardless of time in culture. As in rat optic nerve astrocytes, protoplasmic rat spinal cord astrocytes obtained from embryonic (Sontheimer, unpublished observations) or neonatal cords lack Na^+ channel expression until 5 DIV, show a peak in channel expression at 7 to 8 DIV, and there is a decline in channel density thereafter (Sontheimer et al., 1992a). Fibrous spinal cord astrocytes, like their counterpart in rat optic nerve, are more invariant; and they always show Na^+ channel expression at similar densities. These observations from spinal cord and rat optic nerve suggest that Na^+ channel expression in protoplasmic astrocytes is a transient phenomenon, probably occurring during the second and third week of postnatal development. In contrast Na^+ channels are always expressed by stellate astrocytes, independently of development. The timecourse of Na^+ channel expression in protoplasmic astrocytes may correlate with cell proliferation and the formation of functional gap-junction coupling, a feature that occurs in protoplasmic, but not fibrous, astrocytes (Sontheimer et al., 1990). In hippocampal astrocytes, Na^+ channel expression correlates with the absence of gap-junction coupling: coupled cells lack expression (Sontheimer et al., 1991c). In summary, therefore, it is important to examine channel expression in the context of cell development.

Expression of Astrocyte Sodium Channels is Under Neuronal Control. In the intact brain numerous cell types are in close proximity, sharing a common environment through their common boundaries with the extracellular space. In particular, astrocytes and neurons and their processes can be in close apposition. For example, in rat optic nerve, astrocyte endfeet reach into nodes of Ranvier and are directly apposed to the axolemma (Black et al., 1989). However, patch-clamp recording is almost always done on cultured astrocytes that are deprived of this potentially important contact with surrounding neurons. A number of observations indicate that astrocyte ion channel expression, and particularly the expression of Na^+ channels, is in fact influenced by their neuronal surroundings or by the presence or absence of axons.

Astrocytes cultured from animals in which the optic nerve axons have degenerated following neonatal monocular enucleation show little or no expression of Na^+ currents, whereas Na^+ currents are pronounced in control astrocytes obtained from intact nerves (Minturn et al., 1992) (Figure 12-6). The deprivation of axonal contact not only drastically reduces the density at which Na^+ channels are expressed but also reduces the percentage of cells that show any channel expression at all. As with enucleation, total nerve transsection almost completely abolishes Na^+ currents in astrocytes dissociated from these optic nerves; and this effect can be partially restored if cells are cocultured with neurons (Barres et al., 1990a).

Both procedures described above, enucleation, and nerve transection, lead to a similar complete loss of fibrous (type-2) astrocytes in rat optic nerve. Thus, such studies are limited to Na^+ channel expression in protoplasmic (type-1) astrocytes.

In contrast to the observations on rat optic nerve astrocytes, which suggest that the presence, and/or activity, of axons have a positive modulatory influence on astrocyte Na^+ channel expression, downregulation of Na^+ channel expression by neurons is observed for both subtypes of spinal cord astrocytes (Thio et al., 1993). Thus, coculture of spinal cord astrocytes with dorsal root ganglion neurons, leads within 2 days to a more than 70% reduction in Na^+ current density compared to that of matched control cultures grown in the absence of neurons. Culturing

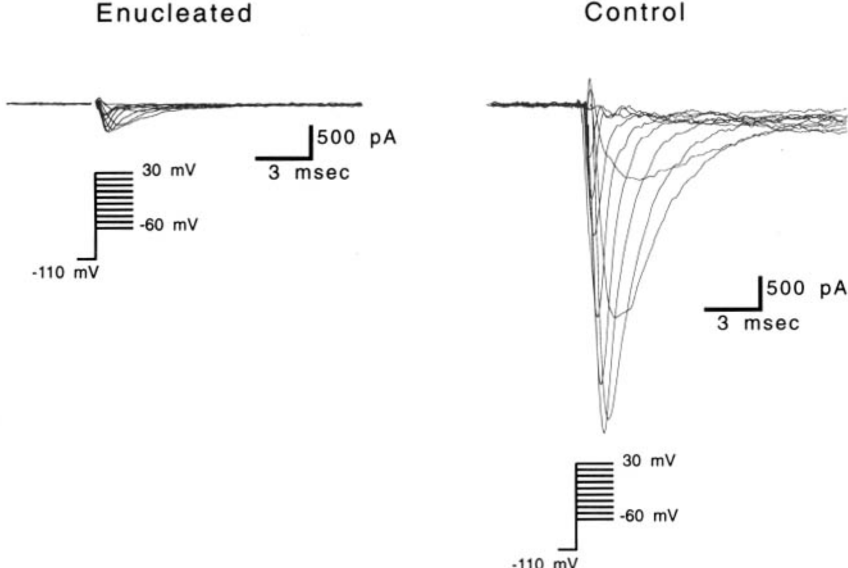

FIG. 12-6. Neuronal influence on astrocyte Na^+ channel expression. Astrocytes cultured from optic nerve following monocular enucleation showed markedly reduced levels of Na^+ currents as compared to cells cultured from control nerves. Enucleation reduced the peak Na^+ currents and the percentage of cells expressing any measurable Na^+ currents. The examples displayed are the largest Na^+ currents recorded in the two groups, and were displayed to scale for better comparison. [From Minturn et al. (1992), with permission.]

cells in the presence of neuron-conditioned medium has a similar, although less potent effect.

It is not known whether the differences observed in the modulatory role of neurons on astrocyte Na^+ channel expression between spinal cord and optic nerve represents an intrinsic, regional difference of astrocytes, or whether the different neuronal/axonal populations account for them. Nor are the means by which neurons control the expression of astrocyte ion channels known; but the potential of neuron-conditioned media to mimic effects of neurons or their processes suggests that a soluble factor must serve as signal.

The above-described influences on the expression of ion channels require hours or days to occur, and are likely to regulate the synthesis of channel protein. Neuronal influences on a much faster time-scale have been observed in frog optic nerve (Marrero et al., 1989). Here, Na^+ currents in glial processes contributing to the glial limitans are transiently facilitated in response to nerve impulses seconds after stimulation, suggesting that fast acting modulatory mechanisms must exist in addition to the slower regulation of channel expression. Again, the means by which this modulation is mediated is unknown.

Astrocytes In Vivo Express Sodium Channels. Almost all studies characterizing voltage-dependent Na^+ channel expression in astrocytes have utilized patch-clamp recordings from astrocytes *in vitro* (cell culture or acutely dissociated cells). In contrast, the classical electrophysiological studies of glial cells by Kuffler and colleagues (Kuffler and Potter, 1964; Kuffler et al., 1966; Orkand et al., 1966), which utilized *in situ* preparations, did not indicate the presence of any voltage-dependent conductances. The apparent discrepancy in these observations raises the question as to whether channel expression may be an epiphenomenon peculiar to cell culture, or perhaps a result of differing recording techniques. A number of laboratories have addressed this question in different ways.

1. Using a polyclonal antibody (7493) directed against rat brain Na^+ channels, Black et al. (1989) have demonstrated the presence of Na^+ channel immunoreactivity in astrocyte processes at nodes of Ranvier in the intact rat optic nerve (Figure 12-6).
2. Barres and colleagues (1990a) have utilized a new "tissue print" dissociation procedure, which allowed them to isolate astrocytes from optic nerve with most of their processes intact and obtain patch-clamp recordings. These cells, like astrocytes in culture, express voltage-activated Na^+, K^+, and Ca^{2+} currents, suggesting that the channels mediating these currents are also expressed *in vivo*. However, as in other dissociation procedures, enzymes were still used to isolate cells, and the recordings were necessarily made in the absence of the natural neuronal environment of the astrocytes. Thus it is still possible that the cultured cells show responses not observed in the intact brain (where, for example, the expression, and/or activity, of ion channels could be suppressed by adjacent neurons).
3. A number of laboratories have started to apply patch-clamp studies to more intact tissue preparations such as whole-mount retina and isolated brain slices. The first such studies on glial cell have demonstrated that voltage-activated Na^+ channels are expressed in glial precursor cells in corpus callosum

slices (Berger et al., 1991) and in identified astrocytes in hippocampal slices (Sontheimer and Waxman, 1992a, 1993; Steinhäuser et al., 1992) (Figure 12-7A). Similarly, astrocytes in the intact rabbit retina have been shown to express Na^+ channels with biophysical characteristics of the Na^+ currents expressed in protoplasmic optic nerve astrocytes (Clark and Mobbs, 1992).

These studies, particularly those *in situ,* seem to dismiss concerns that Na^+ channel expression in glial cells is an artifact of cell culture.

Astrocyte Sodium Channels Are Not Involved in the Generation of Action Potentials. Na^+ channels in excitable cells are responsible for the upstroke of the action potential (Figure 12-7B, D); and no other functions of voltage-activated Na^+ channels are known. Consequently, the expression of such channels by astrocytes raises the question of their ability to generate action potentials. However, astrocytes express Na^+ channels at a density that is typically at least 1 to 2 orders of magnitude lower than in excitable cells, being well below 1 channel per square micrometer (Table 12-2) as compared to tens or hundreds of channels per square micrometer for neurons. Furthermore, the peak Na^+ conductance in neurons is at least equal to the peak K^+ conductance, whereas in astrocytes it is usually 5- to 10-fold smaller than the K^+ conductance (Figure 12-7A, B). This leads to a situation in which the astrocyte resting potential is stabilized in a "voltage-clamp-like" way by its high K^+ conductance, so preventing the activation of Na^+ currents.

In isolated spinal cord astrocyte cultures, proto-

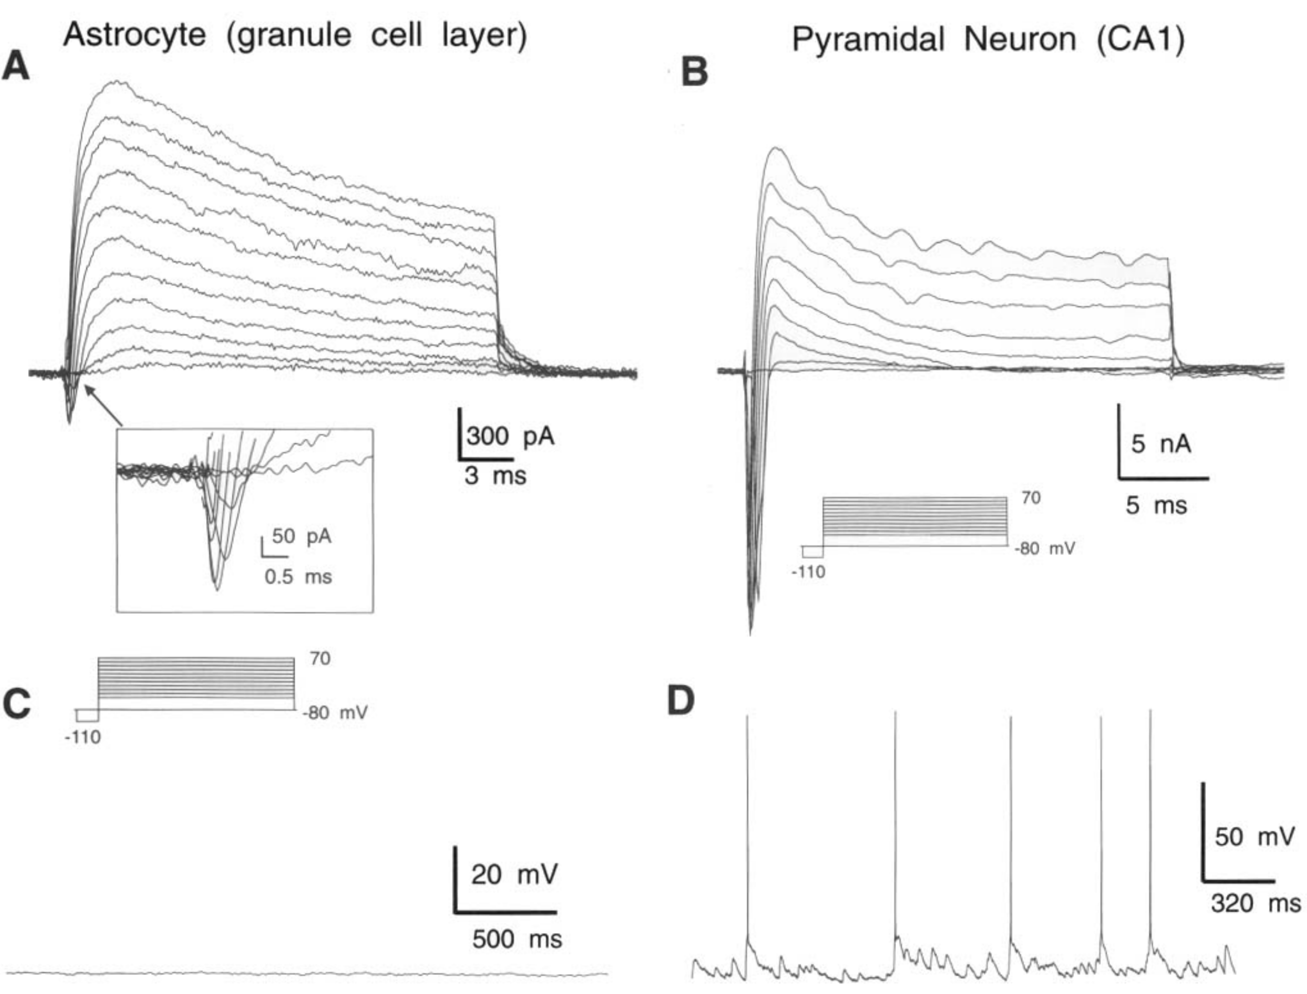

FIG. 12-7. Comparison of typical whole-cell current responses in a representative hippocampal neuron and astrocyte recorded in brain slice. Currents were elicited in response to depolarizing voltage steps to the potentials indicated. Recordings were obtained with a KCl-containing pipette solutions, to allow both Na^+ current and K^+ current activation. In the neuron (*B*) the relative proportion of Na^+ to K^+ currents shows a dominance of Na^+ currents, whereas in the astrocyte (*A*) outward K^+ currents were much larger than inward Na^+ currents. While the neurons displayed spontaneous synaptic activity and fires action potentials (*D*) the astrocyte did not (*C*). [From Sontheimer and Waxman (1993), with permission.]

TABLE 12-2. *Sodium Channel Densities*

Neurons		Astrocytes	
Squid giant axon (Conti et al., 1975)	330	RON Type 1 (Barres et al., 1989)	<0.35
Frog node (Conti et al., 1976)	1900	(Sontheimer et al., 1991a)	<0.25
Rat node (Neumcke and Staempfli, 1982)	700	RON Type 2 (Barres et al., 1988)	<0.1
		(Sontheimer et al., 1991a)	0.25

Values represent channels/ μm^2.

plasmic astrocytes can transiently express very high densities of Na^+ channels during the second week of *in vitro* development (Sontheimer et al., 1992a), with channel densities as large as typically seen in cultured neurons. Indeed action potential-like responses can be recorded from such cells under current-clamp. Potentials more negative than −70 mV are required to elicit such responses to current injection; and the cells never fire spontaneous action potentials. In fact, a mismatch of resting potential (−30 to −40 mV) and steady-state Na^+ current inactivation (h_∞) curve midpoint, (−90 mV) must inactivate the majority of Na^+ channels and render them nonfunctional. As demonstrated above, Na^+ channel expression in these cells is suppressed by the presence of neurons. *In vivo* channels densities may be far too small to generate action potentials, and no spontaneous electrical activity can be recorded in astrocytes *in situ* (Figure 12-7C).

In summary, therefore, it is highly unlikely that astrocytes use Na^+ channels to generate action potentials (see also Chapter 20).

Oligodendrocytes

Although compelling evidence exists that oligodendrocytes share a common precursor cell with stellate astrocytes (Raff, 1989), oligodendrocyte channel expression differs from that of their astrocyte siblings. Thus, as the bipotential glial progenitor cell that expresses voltage-activated channels Na^+ (Sontheimer et al., 1989b; Barres et al., 1990b), Ca^{2+} (Verkhratsky et al. 1990), and numerous types of K^+ channels (Sontheimer et al. 1989b; Barres et al., 1990b) makes a commitment to differentiate into an oligodendrocyte, it abandons the expression of voltage-activated Na^+ and outwardly rectifying K^+ channels (Sontheimer and Kettenmann, 1988; Sontheimer et al., 1989b). As in developing neurons (Konnerth et al., 1987), however, both glial precursor cells and oligodendrocytes (Sontheimer et al., 1989a) express a different class of Na^+ channel, which is insensitive to TTX and largely insensitive to voltage. These pH-activated Na^+ channels [Na_H^+] are gated by a step-acidification of their extracellular milieu (Krishtal and Pidoplichko, 1980). A pH step from pH 7.9 to pH 6.7 induces a large, transient, comparatively slow inward current in glial precursor cells, oligodendrocytes, and neurons, but not in protoplasmic astrocytes or Schwann cells (Figure 12-8). The pH-activated Na^+ currents are potentiated by reduced $[Ca^{2+}]_o$ and show a "run-down" with repeated pH challenges (Sontheimer et al., 1989a). Na_H^+ can be coexpressed with TTX-S voltage-dependent Na^+ channels in precursor cells and neurons, and its expression precedes the expression of voltage-activated channels (Grantyn et al., 1989) during neuronal development. A functional role has not yet been identified for Na_H^+ in oligodendrocytes and neurons.

Glial Precursor Cells

Much attention has been paid to studying electrophysiological properties of cells developing along the oligodendrocyte lineage from the bipotential oligodendrocyte-type 2 *a*strocyte (O-2A) progenitor cells to differentiated oligodendrocytes (Sontheimer et al., 1989b; Barres et al., 1990b). Some of these studies have utilized stage-specific monoclonal anti-

bodies that allow the differentiation of at least two developmental stages of precursor cells and two stages of oligodendrocytes (Sontheimer et al., 1989b); and these studies have demonstrated dramatic changes in channel complement during cell development. In mouse cerebrum (Sontheimer et al., 1989b) and rat optic nerve (Barres et al., 1990b), precursor cells are characterized by a large complement of channels, including TTX-S Na^+ channels and 3 types of K^+ channels (K_d, K_a, and K_{ca}). Mouse cerebrum precursor cells may also express L- and T-type Ca^{2+} channels (Verkhratsky et al., 1990b). As precursor cells differentiate to oligodendrocytes, these channels are lost and replaced by inwardly rectifying K^+ channels (Sontheimer et al. 1989b) which constitute the major channel type in differentiated oligodendrocytes *in vitro* (Barres et al., 1990b; Sontheimer et al., 1989b) and *in situ* (Berger et al., 1991; Sontheimer and Waxman, 1993).

WHAT IS THE FUNCTION OF SATELLITE CALCIUM AND SODIUM CHANNELS?

Calcium Channels

The central role of transmembrane Ca^{2+} currents in so many physiological processes is now well established for a wide variety of tissues; one must presume, therefore, that such currents play similar important roles in satellite cells. What these specific roles are, however, remains unclear. This is partly because even though the channels are present in the membrane of astrocytes and Schwann cells *in vivo* the existence of Ca^{2+} *currents* is open to question. For there is the problem for both T-type and L-type Ca^{2+} channels (shared with Na^+, K^+, and Cl^- voltage-gated channels) that their apparent activation thresholds (−60mV and −30mV, respectively) are considerably more depolarized than the reported astrocytic resting potential (of about −80mV). When would they ever be open to any significant extent? The answer may be that not all astrocytes have resting potentials of the order of −80 mV (at least not all of the time). Certainly during *intense* electrical neuronal activity, the depolarization produced might well be sufficient to activate these channels. Under certain spreading-depression-like pathological conditions such as associated with ischemia, trauma, anoxia, or hypoglycemia, extracellular K^+ concentration can rise to 80 mM (Somjen, 1979 for review), and under those conditions depolarizations would certainly be large enough to activate glial Ca^{2+} channels.

In spite of these gaps in our knowledge, there can be little doubt that changes (even small ones) in cytosolic Ca^{2+} concentrations must be important not just for the household functions of the glial cell but also in its interaction with neurons. Indeed, the coculturing experiments (Corvalan et al., 1990) suggest that experiments with purified cultures of astrocytes may not be best for determining the functions *in vivo*, where the glial cells are in intimate contact with neurons. But speculation on these points requires a more solid base provided by future experimentation.

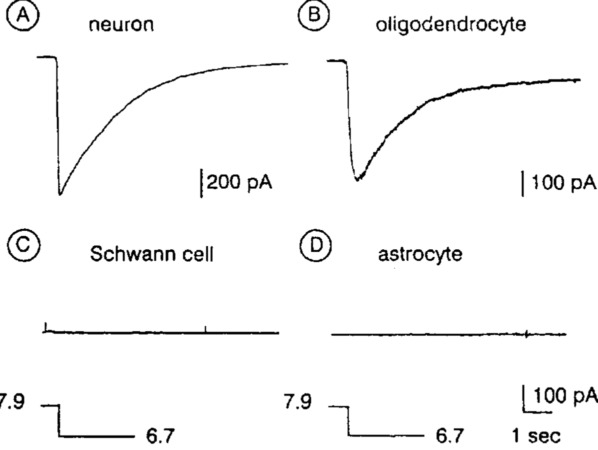

FIG. 12-8. Proton activated Na^+ channels are expressed in oligodendrocytes. Neurons (A) and oligodendrocytes (B) in contrast to Schwann cells (C) and astrocytes (D) express proton-activated Na^+ channels. Stepwise changes of the external pH from 7.9 to 6.7 were applied and resulted in the inward currents displayed. All recordings were taken in the presence of 1 μM TTX at a holding potential of −70 mV. Extracellular Ca^{2+} was 0.1 mmol, Mg^{2+} was omitted.

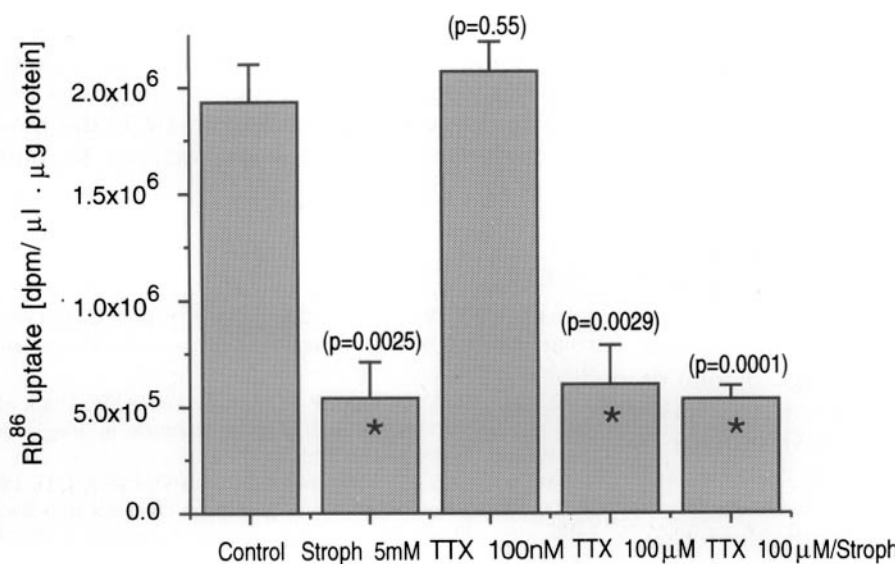
Sodium Channels

In astrocytes the membrane resting potential is quite high, being −75 to −85 mV (Ballanyi et al., 1987). In Schwann cells and glial precursor cells, however, the resting potential (in mouse, rat, and rabbit) is much smaller, between −40 mV and −50 mV (Konishi, 1989; Howe and Ritchie, 1990; Verkhratsky et al., 1991). This means that the Schwann cell Na^+ channels cannot be involved in any regenerative action such as nerve impulse conduction because they would be completely inactivated. Astrocyte Na^+ channels, because of the more favorable membrane potential, would not be inactivated; but the low channel density (see above) would again exclude action potential generation. Of course, the satellite cell Na^+ channels may have no function other than to confuse electrophysiologists; but such speculation is unprofitable. One highly speculative suggestion is that the satellite cells, particularly the Schwann cells, synthesize these channels, which they cannot use, for

later transfer to the neighboring axolemma where they will be used in the process of conduction (Gray and Ritchie, 1985). This local source of sodium channels would supplement (but not replace) the more generally accepted supply by axoplasmic transport from the neuronal cell body in conditions where this transport might be insufficient, especially for the more distal parts of the axolemma, which in man may be as far as one meter from the cell body. Such a neuron would have to supply 500 to 2000 nodes with channels, each with a lifetime of just over 3 days (see Figure 12-2). Apart from the clear economic advantage of such channel transfer, there are at least two pieces of circumstantial evidence in its favor. First, it is known that large molecules the size of proteins can be transferred between axoplasm and



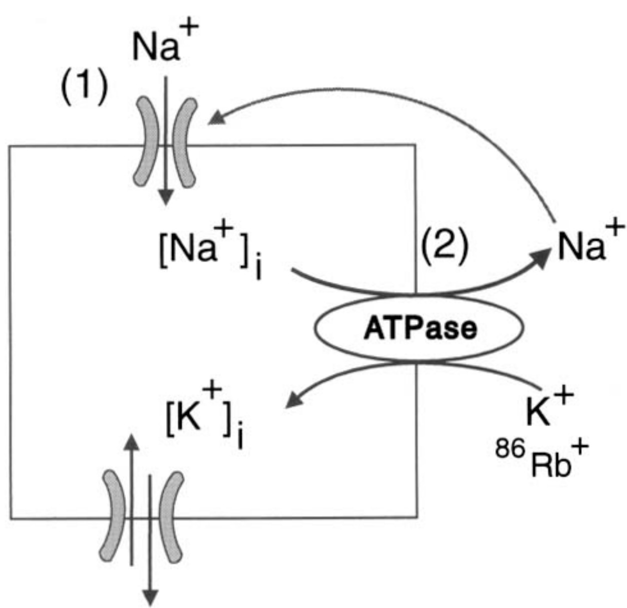


FIG. 12-9. Evidence for function of Na^+ channels as "return" pathway for Na^+/K^+-ATPase. **(A)** Na^+/K^+-ATPase activity was measured as unidirectional influx of $^{86}Rb^+$. $^{86}Rb^+$ uptake determined in spinal cord astrocytes following 15 minutes incubation with the isotope in combination with TTX, *strophanthidin or* TTX, and strophanthidin in combination at the concentrations indicated. (Significant changes in flux were indicated with * and *p*-values plotted next to error bars which represent SEM). Strophanthidin, 100 µM TTX as well as both drugs in combination showed similar reduction in $^{86}Rb^+$ uptake, while 100 nmol TTX did not alter $^{86}Rb^+$ uptake significantly. **(B)** Simplified cell model to explain Na^+ channel-Na^+/K^+-ATPase coupling in spinal cord astrocytes. Na^+ channels function to maintain intracellular Na^+ $[Na^+]_i$ at levels that provide a substrate for Na^+/K^+-ATPase. TTX blocks Na^+ channels (*1*), while strophanthidin and ouabain interfere with activity of the ATPase (*2*).

Schwann cell cytoplasm (Grossfeld, 1991). Although this is different from transfer between Schwann cell plasmalemma and axolemma, at least it is a step in the right direction. Second, there is the morphological finding (Landon and Hall, 1976; Chapter 3, this volume) that the Schwann cell in the nodal region sends a regular hexagonal array of microvilli down onto the axolemma. Although no direct contact between them has yet been shown, the two cell membranes (Schwann cell plasmalemma and axolemma) approach each other much more closely than apposed cell membranes usually do (Landon and Hall, 1976). Indeed, Figure 12-3B clearly shows a section through these microvilli heavily stained with the Na^+ channel antibody. A similar situation applies in the case of astrocytes where Na^+ channel immunoreactivity is observed in astrocyte processes in close apposition to the axolemma at nodes of Ranvier (Black et al., 1989).

Despite its attractiveness, however, the evidence for the transfer theory so far is indirect and speculative. Direct evidence could be provided by molecular biology from a comparison of the molecular structure of the Schwann cell and axonal Na^+ channels—but this is yet to come. It should be pointed out again that from the electrophysiological point of view the Schwann cell Na^+ channels seem to be identical to those in axons (apart from the shift in the *I-V* curve mentioned above). Thus both channels activate with similar kinetics, both have multiple inactivation states, both have similar affinities for tetrodotoxin and saxitoxin. This similarity also extends to potassium channels. Both Schwann cell and axon display an inward rectifier; and both have three types of delayed rectifier channel corresponding with the three types of potassium channel described for frog nerve by Dubois (1981), namely, G_{Kf1}, G_{Kf2}, G_{Ks} (Baker et al., 1993). Again, the molecular identity of the satellite cell and axonal channels remains to be established.

Since astrocyte Na^+ channels are unlikely to be directly engaged in action potential generation, their role is an enigma. It is conceivable, however, that astrocyte Na^+ channels serve roles that do not require regenerative voltage-dependent activation. For at any resting potential a small (but finite) Na^+ permeability must exist, sufficient to allow a small amount of Na^+ ions to leak into the cell (Hille, 1992). Such a Na^+ leak may be important for providing Na^+ ions in high enough concentration for functioning of the astrocyte Na^+/K^+-ATPase, which requires binding of intracellular Na^+ ions to complete its cycle. Indeed, such an involvement of Na^+ channels in the Na^+/K^+-ATPase cycle is known for cultured spinal cord astrocytes (Sontheimer et al., 1994) (Figure 12-9). Thus experiments using the unidirectional influx of $^{86}Rb^+$ as a measure for Na^+/K^+-ATPase activity, show that TTX reduces ATPase activity in a dose-dependent manner. Indeed, at concentrations sufficient for complete Na^+ channel block, TTX is as effective in blocking the Na^+/K^+-ATPase activity as ouabain or strophantidin (Figure 12-9A). This suggests a model (Figure 12-9B) where a Na^+ leak through voltage-activated Na^+ channels maintains the Na^+/K^+-ATPase operational. This is important since one of the main functions of the glial Na^+/K^+-ATPase is believed to be the uptake and removal of extracellular K^+ during spatial buffering. Elevated $[K^+]_0$ would increase the amount of Na^+ ions entering through Na^+ channels since their open probability increases with increasing depolarization. This would stimulate the pump, which in turn would remove extracellular K^+ more rapidly. In this model, therefore, Na^+ channels would facilitate K^+ buffering by the ATPase.

13 Distribution and transport of chloride and bicarbonate ions across membranes

WOLFGANG WALZ

In the first accounts of glial physiological properties, Cl^- ions were not thought to be involved in the genesis of the membrane potential, or in the function of cellular K^+ homeostasis (Kuffler and Nicholls, 1966). This conclusion was based on the fact that the membrane potential of glial cells showed the same behavior in normal as in Cl^--free salt solution. Additionally, removal of Cl^- ions did not result in any significant membrane potential changes. Over the years, however, more information on the role of Cl^- surfaced (Kimelberg et al., 1979; Kimelberg, 1981; Walz and Schlue, 1982). In addition, with the acceptance of the concept that glial cells not only distribute K^+ passively but also accumulate K^+ and store it transiently, the role of Cl^- became more interesting. The accumulation of K^+ had to be electroneutral and the Na^+ concentration in glial cells was too low to account for a simple 1:1 Na^+:K^+ exchange. It was also found that glial cells could swell rapidly and that Cl^- was involved in this swelling (see Kimelberg and Ransom, 1986; see Chapter 61, this volume). Then Bevan et al. (1985) discovered that under certain circumstances glial cells demonstrated a large permeability for Cl^- ions, stimulating speculations about the functional role of Cl^- channels. Thus, today the question of the role of Cl^- in glial function is a complex one and it looks as if at least two of the three K^+ removal mechanisms involve Cl^- and one also involves HCO_3^- (Walz, 1992). This chapter summarizes the major recent advances in our knowledge about Cl^- and HCO_3^- distribution and transport, as well as function. It should be noted that in the past few years excellent reviews have appeared on this subject (Kettenmann, 1990; Kimelberg, 1990).

DISTRIBUTION

Cerebrospinal fluid in man contains about 119 mM Cl^- (Fishman, 1980), while the Cl^- concentration in rat brain was measured as 134 mM (Smith et al., 1981). Both values are reasonably close to the approximately 140 mM Cl^- that most physiological salt solutions contain. The leech central nervous system, which is directly situated in the blood sinus, does not have a blood-brain barrier. It was found by Zerbst-Boroffka (1970) that leech blood contains only 36 mM Cl^-, with the rest of the anions consisting of high concentrations of lactate, succinate, fumarate, bicarbonate, and citrate. Thus, most artificial salt solutions of researchers working with isolated leech ganglia employ unphysiologically high Cl^- concentrations. Intracellular Cl^- content or concentration were measured by two different methods, radioactive ^{36}Cl flux measurements or the use of Cl^--sensitive microelectrodes. The use of ^{36}Cl is quite straightforward as long as homogeneous monolayer cultures are used, but there are problems in the measurement of cell volume and the calculation of intracellular Cl^- concentration. Almost all researchers working with Cl^--sensitive microelectrodes use the Corning 477315 exchange resin. This charged-carrier exchanger is a quaternary ammonium compound, the precise formulation of which has not been revealed. This exchanger is sensitive to quite a few anions, the most notable is HCO_3^-. Thus, in order to measure the intracellular Cl^- concentration properly, one has to work in nominally HCO_3^--free solutions. These HCO_3^--free conditions are bound to influence the Cl^- gradient due to inhibition of Cl^-/HCO_3^- exchange. A passive Cl^- distribution would result in an intracellular Cl^- concentration of about 5 mM due to the high resting potential. In order to judge if Cl^- is passively distributed [i.e., the chloride equilibrium potential equals the membrane potential ($E_{Cl} = E_M$)] or actively accumulated across a glial cell membrane, the best strategy would be to apply an inhibitor of Cl^- transport (furosemide or bumetanide) and determine if the Cl^- concentration changes to a new value more compatible with passive distribution or if the inhibitor does not change the Cl^- concentration. This approach was used with several preparations (see Table 13-1). In neuropile glial cells of the leech E_{Cl} and E_M are not significantly different, and bumetanide has no effect on the Cl^- concentration (Ballanyi and Schlue, 1990). In cultured oligo-

TABLE 13-1. *Cl^- Distribution and Permeability in Different Glial Cell Preparations*

Preparation	Distribution	Permeability relative to K^+
Leech neuropil glial cells	Passive	High
Glial cells in drone retina	Passive	High
Glial cells in frog spinal cord	Passive	?
Glial cells in olfactory cortex slice	Passive	High
Astrocytes in hippocampal slice	Accumulation	?
Cultured oligodendrocytes	Accumulation by 2–3 mM	Medium
Cultured astrocytes	Accumulation by ~30 mM	Low
Glial cells in cerebral cortex *in vivo*	Accumulation by ~35 mM	?

For references see text.

dendrocytes, measurements with microelectrodes indicated that the intracellular Cl^- concentration was 2 to 3 mM higher than expected if distribution was passive. If the cells were treated with bumetanide their E_{Cl} and E_M were no longer significantly different and the internal concentration decreased by 2 to 3 mM (Hoppe and Kettenmann, 1989a, 1989b). In cultured astrocytes, several reports found ^{36}Cl distributions that are compatible with a 31 to 50 mM intracellular Cl^- concentration (Kimelberg et al., 1979; Kimelberg, 1981; Walz and Hertz, 1983). Application of SITS (4-acetamid-4′-isothiocyanostilbene-2,2′-disulfonic acid) (Kimelberg, 1981) lowers the Cl^- concentration and application of furosemide results in a passive Cl^- distribution (Walz and Hertz, 1983). Measurements with Cl^--sensitive microelectrodes gave a concentration range of 20 to 40 mM in cultured astrocytes (Kettenmann et al., 1987). In this respect, it is of interest that an *in vivo* study (Smith et al., 1981), using rat cerebral cortex, measured the total ^{36}Cl content. The study used the assumptions that the extracellular space is 14% of the total brain volume, that the relative neuron to glial volume is 2:1, and that Cl^- is passively distributed in neurons. It was calculated that the glial intracellular Cl^- concentration of the cortex is between 36 and 46 mM, a result that is close to the measurements of cultured astrocytes, but not of cultured oligodendrocytes. Astrocytes in the hippocampal slice were also found to exhibit active Cl^- accumulation by an indirect method (MacVicar et al., 1989): these cells possess a $GABA_A$ receptor and upon its activation they depolarize. Since this has to involve Cl^- efflux, a nonpassive Cl^- distribution can be assumed. In glial cells of the drone retina, E_{Cl} and E_M are identical (Coles and Orkand, 1984). In the *in vivo* frog spinal cord, unidentified glial cells show a passive distribution of Cl^- (Bührle and Sonnhof, 1983). Unidentified glial cells of olfactory slices have a significantly more positive E_{Cl} than E_M (Grafe and Ballanyi, 1987). However, once the interference of other anions is taken into consideration, the newly corrected E_{Cl} and the E_M are in close correspondence, and one has to assume passive distribution. Unfortunately, the authors did not apply furosemide or bumetanide.

The experiments on Cl^- distribution are summarized in Table 13-1. It is obvious that there is no clear picture about the Cl^- distribution in these different glial preparations. The two invertebrate systems clearly show passive distribution as does the frog spinal cord. Unexplained are the contradictory results from mammalian cortex: *In vivo,* slice and culture preparations show nonpassive distribution for glial cells with the exception of glia in the olfactory cortex slice. However, the Cl^- accumulation of cultured oligodendrocytes is minimal. Such a small accumulation could be easily hidden in the measurements of Ballanyi and coworkers, which would indicate that the unidentified glial cells they were working with could have been oligodendrocytes. It is also quite clear that the Cl^- distribution across astrocytic and oligodendrocytic membranes is very much different. The Cl^- accumulation is accomplished by the Na^+-K^+-Cl^- cotransport system as the inhibitory effect of furosemide and bumetanide indicates. There is also a small contribution by the Cl^-/HCO_3^- exchange transport (Kimelberg, 1981).

The HCO_3^- concentration of human cerebrospinal fluid was measured as 22 mM (Fishman, 1980), which is close to the 26 mM of conventional physiological salt solutions. Intracellular bicarbonate content can be measured in monolayer cultures, since the rapidly equilibrating CO_2 will keep E_{H^+} and $E_{HCO_3^-}$ equal as long as the carbonic anhydrase is not inhib-

ited. Thus one can calculate the intracellular bicarbonate concentration:

$$[HCO_3^-]_i = 10(pH_i - pH_0) \times [HCO_3^-]_0$$

Using this method cultured astrocytes were shown to have an accumulation of 11 mM HCO_3^- and an $E_{HCO_3^-}$ of −27 mV with an extracellular HCO_3^- concentration of 26 mM, which is close to cerebrospinal fluid levels (Walz, 1992).

RESTING PERMEABILITY

The data in Table 13-1, which permit an evaluation of the Cl^- permeability of glial cell membranes, show that those with passive distribution have a high permeability, while those which accumulate intracellular Cl^- have a low permeability. A high Cl^- permeability is usually demonstrated by displacing the membrane potential either by high K^+ or barium application. If there is indeed a high permeability, the E_{Cl} will, within seconds, follow the new E_M. In neuropil glial cells, E_{Cl} follows E_M with a lag of less than 30 seconds (Ballanyi and Schlue, 1990). The same holds true for glial cells of the drone retina (Coles and Orkand, 1984). In unidentified glial cells of the olfactory cortex, E_{Cl} changes with a lag time of less than 10 seconds (Ballanyi et al., 1987). Cultured oligodendrocytes seem to have an intermediate position. If the E_M is changed, E_{Cl} will follow with a lag time of a few minutes (Hoppe and Kettenmann, 1989a, 1989b). In cultured astrocytes, the intracellular Cl^- concentration did not change following displacement of the membrane potential (Kettenmann, 1987). Moreover, ^{36}Cl unidirectional influx analysis of cultured astrocytes showed that 77% of the influx was inhibited by furosemide (an inhibitor of Na^+-K^+-Cl^- cotransport and HCO_3^-/Cl^- exchange), indicating only a small channel-mediated component (Walz and Hertz, 1983).

There is no indication of HCO_3^- conductance in normal glial cells. A previous report (Astion et al., 1987) of a considerable HCO_3^- resting membrane conductance in glial cells of the optic nerve of *Necturus* was reinterpreted by the authors (Astion and Orkand, 1988) as the activity of a Na^+/HCO_3^- cotransport. This transport has a stoichiometry of HCO_3^- to Na^+ that is greater than 1, resulting in HCO_3^- effects on the membrane potential.

VOLTAGE-ACTIVATED ANION CHANNELS

As can be seen from the above discussion, under resting conditions astrocytes in culture have a relatively low Cl^- permeability. There are, however, reports that Cl^- channels can be activated in the cell membranes of astrocytes during certain circumstances. Such a Cl^- conductance was first shown for Schwann cells (Gray et al., 1984). Bevan et al. (1985) were the first to study chloride channels in cultured astrocytes with whole-cell clamp techniques. They found a Cl^- inward flux (outward current) that was activated by potentials of −40 mV or more positive and which did not inactivate. Ascorbate, gluconate, and acetate did not pass through that channel; however, isethionate had a substantial permeability. Unfortunately, the presence of an HCO_3^- permeability was not tested by any of the authors. This indicates an anion channel rather than a specific Cl^- channel. SITS and DIDS (4,4′-diisothiocyanostilbene-2,2′-disulfonic acid) inhibited the anion channel. The authors observed too that the whole cell current increased gradually in the 5 to 10 minutes after establishing the seal. Thus, it appeared that intracellular dialysis was removing an inhibitory factor. All these observations are similar to those in the Schwann cells. Other studies (Nowak et al., 1987; Sonnhof, 1987) investigated this large anion conductance of astrocytes at the single-channel level. The single conductance was about 400 to 600 pS. Here it was found that the channel was not noticeable in cell-attached patches, but several minutes after membrane isolation by forming an inside-out patch, the channel openings gradually increased. The existence of these channels in a glial cell *in vivo* preparation was shown by Marrero et al. (1991).

There is some evidence for other Cl^- channels, some of them mediating outward rather than inward currents. Nowak et al. (1987) observed small conductance channels, which were opened by hyperpolarization with 5 pS single-channel conductance. Barres et al. (1988, 1990) found in excised patches from type-1 astrocytes, type-2 astrocytes and oligodendrocytes from the rat optic nerve Cl^- outward currents (Cl^- inward movement) with a single-channel conductance in the range of 25 to 60 pS (see Figure 13-1).

Recently it was shown that cultured rat astrocytes have an anion channel of 200 to 250 pS mediating Cl^- outward movements (Jalonen et al., 1992). The channel is activated by depolarizations, and it is more readily activated when hypoosmotic rather than isosmotic conditions are used. This channel is, like all other single anion channels studied in glial cells so far, only activated in the excised patch. This phenomenon is not yet understood. In their whole-cell clamp studies, Bevan et al. (1985) used pipettes containing ATP, cAMP, and vasoactive intestinal peptide and found no effect on the development of the whole-cell Cl^- current.

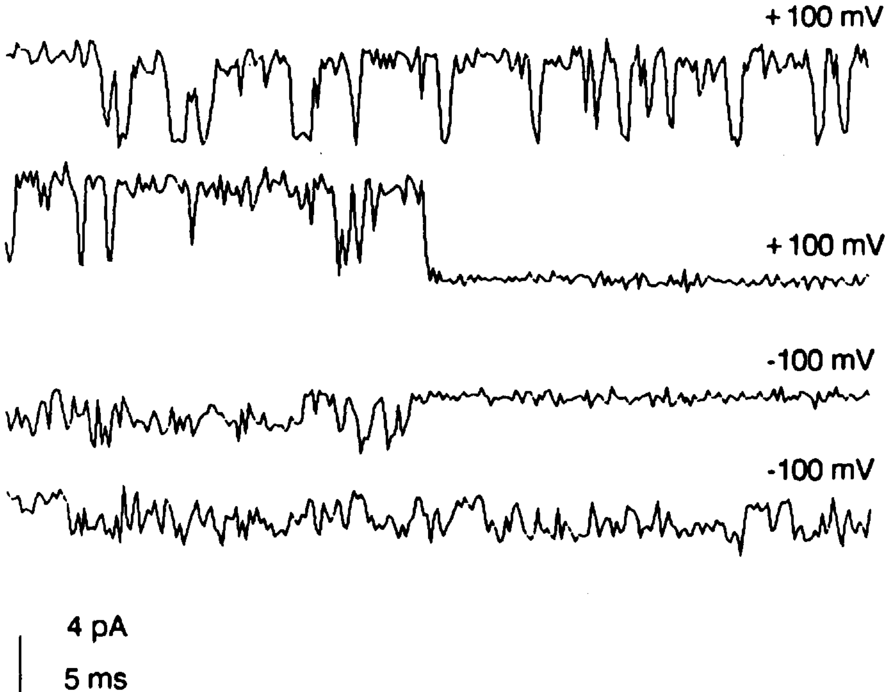

FIG. 13.1 Chloride channel in type-1 astrocytes from rat optic nerve. Single channel recording in an inside-out patch in symmetric TMA-Cl. Channel openings at a holding potential of +100 mV (*top two traces*) have larger amplitudes than those at −100 mV (*lower two traces*). [From Barres et al. (1990), with permission.]

TRANSMITTER-GATED CHLORIDE CHANNELS

α-Adrenergic agonists cause a depolarization in astrocytes (Bowman and Kimelberg, 1988). The authors found that the reversal potential of the response depended on the E_{Cl}; they also were able to change the response by manipulating the extracellular Cl^- concentration. They concluded that α-adrenergic agonists exert their action by opening Cl^- channels.

Gamma-aminobutyric acid (GABA) depolarizes astrocytes (Kettenmann et al., 1987; see also Chapter 21, this volume). The depolarization of astrocytes reverses at the E_{Cl}. The reversal potential is also shifted by changes in the extracellular Cl^- concentration. Patch-clamp recordings from astrocytes (Borman and Kettenmann, 1988) showed that GABA is directly acting on a receptor similar to, but not identical with, the neuronal $GABA_A$ receptor, which is coupled to Cl^- channels. In cultured oligodendrocytes, GABA application triggers an efflux of Cl^-. The intracellular Cl^- concentration falls from 9.2 by 1.3 mM to be close to the E_{Cl}. It appears that this GABA-activated channel is also permeable for HCO_3^-. Kaila et al. (1991) demonstrated that rat astrocytes responded with an acidosis when exposed to muscimol, a $GABA_A$ agonist. This reflects outflux of HCO_3^- through the GABA-activated channel.

Short application of the neurokinin receptor agonist substance P leads to a biphasic depolarization of cultured astrocytes. The rapid and transient depolarization component lasted a few seconds with a reversal potential close to the potassium equilibrium potential (E_K) (Backus et al., 1991). Single-channel recordings increased the opening time of Cl^- channels. It was concluded that activation of neurokinin receptors in astrocytes modulates the activity of K^+ and Cl^- channels, leading to a complex depolarization of the membrane potential.

POSSIBLE FUNCTION OF CHANNEL-MEDIATED CHLORIDE FLUXES

Boyle-Conway Mediated Potassium Chloride Uptake

Glial cells are involved in K^+ clearance of the extracellular space (Walz, 1989; see Chapter 47, this volume). A spatial buffer mechanism is in all likelihood operating in cells that have a high and selective K^+ permeability. As can be seen from Table 13-1, there are at least three types of glial cells that have a high resting Cl^- permeability. Walz (1982) was the first to suggest (based on the high Cl^- permeability of leech neuropile glial cells) that these cells can take up KCl passively if the extracellular K^+ is increased. This would involve channel-mediated KCl inward movements until $E_K = E_{Cl}$. Since that time, intracellular K^+ and Cl^- measurements showed that an extracellular K^+ increase results in KCl movements into the glial cells, presumably mediated passively through channels. In glial cells of the drone retina (Coles et al., 1986), glial cells from the olfactory cortex slice (Ballanyi et

al., 1987), neuropile glial cells of the leech (Wuttke, 1990), and cultured oligodendrocytes (Hoppe and Kettenmann, 1989a), it was shown that the main response to physiological stimuli or small extracellular K^+ increases was an increase in the concentration of KCl in glial cells. These four preparations are the only ones to show a high or medium Cl^- resting permeability. This suggests that one main function of this Cl^- permeability is the mediation of passive KCl increase during neuronal activity. One result of this function would be a concomitant cell swelling.

Such a Boyle-Conway-mediated KCl uptake could also play a role in glial cells with no measureable resting Cl^- permeability. In this case a large depolarization would be needed to open the large anion conductance channel (see Figure 13-2). To reach the −40 mV of the membrane potential at which these channels are usually activated one would have to increase the extracellular K^+ concentration to approximately 35 mM, a concentration that occurs only in pathophysiological events like hypoxia-ischemia, spreading depression, and trauma. Another problem is the mechanism that keeps these channels normally closed. One would have to postulate an intracellular regulatory mechanism that would remove this block. Bevan et al. (1985) were the first to suggest such a mechanism. There is some experimental evidence for this. If astrocytes in culture are exposed to 60 mM K^+, their K^+ increases by 45 mM. The Cl^- concentration increases by 20 mM and the HCO_3^- concentration by 22 mM (Walz and Mukerji, 1988; Walz, 1992). If Cl^- is replaced by gluconate, the K^+ increase is inhibited by 50%, and if isethionate (which has a high permeability for the anion channel) is used as substituent, the K^+ accumulation rates are not affected. Thus, the authors postulated a Boyle-Conway mediated K^+, Cl^- and HCO_3^- increase accompanied by a 40% volume increase. The pathophysiological implications of this mechanism are obvious, although one has to point out that a 40% swelling is only observed in cell cultures, whereas *in vivo* the extent of the swelling will be much reduced.

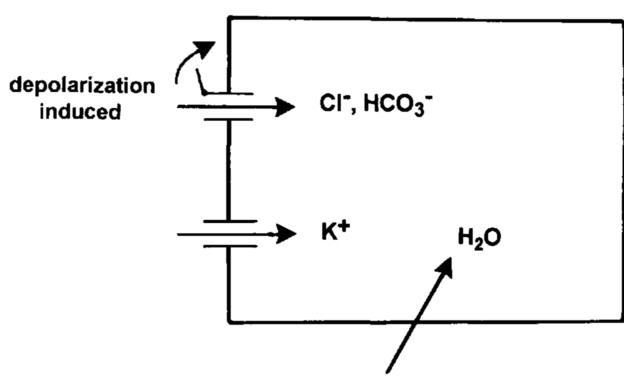

FIG. 13-2. Scheme of a Boyle-Conway mediated anion and K^+ accumulation involving the large anion conductance.

Neurotransmitter-Evoked Release of Potassium Chloride

Bormann and Kettenmann (1988) postulated a model of Cl^- regulation by glial cells at GABAergic synapses. The activation of postsynaptic neuronal GABA receptor channels induces an inwardly directed movement of Cl^-. Glial cells in the vicinity of the synaptic cleft react with efflux of Cl^-, which could buffer the loss of Cl^- from the extracellular space. The physiological significance of this buffering is, however, questionable. With a Cl^- concentration of about 140 mM in the extracellular space, the relative Cl^- changes are small and no processes sensitive to such changes are known.

Other authors (Bowman and Kimelberg, 1988) favor the concept that KCl release from astrocytes exposed to GABA and glutamate would serve to influence neuronal excitability. Walz (1982) postulated that a transmitter-evoked release of KCl from leech neuropil glial cells could serve as the return signal for glial cells to release temporarily stored K^+ back into the extracellular space for its eventual return into neurons.

CHLORIDE-BICARBONATE EXCHANGE AND SODIUM-BICARBONATE COTRANSPORT

These two anion transport mechanism are closely involved in internal and external pH regulation (see Figure 13-3). Kimelberg et al. (1979) and Kimelberg

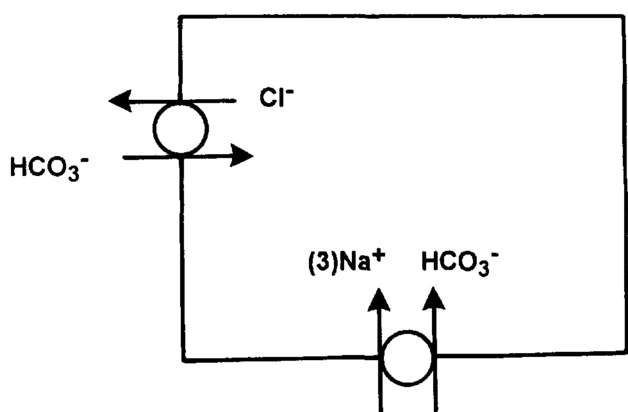

FIG. 13-3. Scheme of carriers involving HCO_3^- transport.

(1981) presented evidence for a SITS-inhibitable Cl^-/HCO_3^- and Cl^-/Cl^- exchange. The Cl^-/Cl^- exchange might be due to the inhibition of Cl^- channels by SITS (Bevan et al., 1985) and might therefore be nonexistent. However, the evidence for the Cl^-/HCO_3^- exchange was convincing. Measurements on leech neuropile glial cells (Deitmer and Schlue, 1987, 1989) demonstrated that this Cl^-/HCO_3^- exchange was a Na^+-dependent Cl^-/HCO_3^- exchange, with a steep dependency on intracellular pH. The exchange mechanism is electroneutral with the energy being provided by the Na^+ gradient (Thomas, 1984). Kettenmann and Schlue (1988) failed to find evidence for this exchange mechanism in cultured oligodendrocytes. This exchange mechanism couples Cl^- and pH regulation.

A Cl^--independent pH regulation is provided by the Na^+-HCO_3^- cotransporter, which is also SITS and DIDS sensitive (except in cultured oligodendrocytes) (Kettenmann and Schlue, 1988). Deitmer and Schlue (1989) found evidence for such an electrogenic Na^+-HCO_3^- cotransport in leech glial cells (either 1:2 or 1:3 coupling ratio Na^+:HCO_3^-). The same was found for glial cells in the mudpuppy optic nerve (Astion and Orkand, 1988). In cultured oligodendrocytes this cotransport seems to be electrically neutral (Kettenmann and Schlue, 1988). The electrogenic nature of the transporter makes its action dependent upon the membrane potential. A depolarization will stimulate its turnover rate. Deitmer (1991) found in leech glial cells that the cotransport can reverse its action and lead to HCO_3^- secretion from the cells (see Chapter 14, this volume).

SODIUM-POTASSIUM-CHLORIDE COTRANSPORT

The first direct evidence for an electroneutral, coupled transport of Na^+, K^+, and Cl^- together, came from work by Geck et al. (1980) on mouse tumor ascites cells. The authors described net fluxes of Na^+, K^+, and Cl^-, which were furosemide-sensitive. The ratio between the fluxes did not vary with the concentration of the ions, and the movement of any one ion required the presence of the other two. Moreover, the fluxes were unaffected by the membrane potential and vice versa. Accordingly, Geck et al. (1980) proposed an electroneutral triple cotransport of Na^+, K^+, and Cl^- in the proportions 1:1:2, respectively. Since 1980, this cotransport was demonstrated, in many tissues, and is reputed to play a role in functions such as epithelial absorption, secretion, cell volume regulation, and intracellular Cl^- accumulation.

Kinetic Properties

The existence of a furosemide-sensitive Cl^- and K^+ transport in astrocytes was first described by Kimelberg (1979). A detailed study of the kinetics of the carrier in cultured rat astroyctes was made by Tas et al. (1986, 1987). These authors found that about 30% of the unidirectional K^+ flux was sensitive to furosemide during steady-state conditions. With the use of Hill plots for Na^+, K^+, and Cl^- the authors found the Hill coefficients for Na^+, K^+, and Cl^- to be 1.06, 0.99, and 1.90, respectively. These values are close to the theoretically predicted stoichiometry of 1:1:2, confirming the action of a true Na^+, K^+, and Cl^- carrier and not another form of a furosemide-sensitive transport. The authors also found that only Br^- could replace Cl^- and that gluconate and acetate were ineffective, in agreement with reported properties of the carrier in other systems. An analysis of the activity of the Na^+, K^+, and Cl^- cotransporter on the extracellular concentrations of these ions gave the following $K_{0.5}$ values: the half-maximal activation concentration for K^+ was 2.7 mM; the one for Na^+ was 35 mM; and the one for Cl^- was 40 mM. It is of special interest to point out that the $K_{0.5}$ is almost identical with the K^+ concentration (3 mM) in the cerebrospinal fluid. Thus, small increases of extracellular K^+ would have a maximal stimulatory effect on the carrier, resulting in K^+ uptake into astrocytes.

Involvement in Volume Control

The involvement of the carrier in volume changes of rat astrocytes was investigated by Kimelberg and Frangakis (1985). Increasing the osmolarity of the medium from 320 to 520 mOsm by addition of mannitol resulted in shrinkage of the cells. Maximum shrinkage occurred within 5 minutes, reaching a new steady state of 0.78 μl/mg protein from an initial value of 1.96. The same treatment had no effect on the Cl^- content. Thus, the cells appear to be behaving as osmometers, responding with marked shrinkage to exposure to hypertonic medium due, presumably, to loss of water. The presence of 1 mM furosemide had no significant effect. Exposure of the cells to hypotonic medium resulted in cell swelling. This was followed by considerable recovery of volume (regulatory volume decrease). Furosemide did not affect the volume recovery. After reexposure to isotonic medium, the cells shrank rapidly and then began to return to their original volume. This restoration of volume was partially inhibited by furosemide. There was also an initial rapid loss of K^+ in hypotonic medium. This was then followed by reuptake of K^+, when the cells were subsequently ex-

posed to isotonic medium. The reuptake of K^+ after exposure to isotonic medium was partially inhibited by furosemide, similar to its effects on the recovery of the water space under the same conditions. Thus, there is compelling evidence that the $Na^+/K^+/Cl^-$ carrier is involved in volume regulation in astrocytes. However, this happens only during the secondary volume recovery after previous cell shrinkage due to exposure to isotonic medium, in cells which have already been exposed by hypotonic medium.

Active Chloride Accumulation

Walz and Hertz (1983) measured the Cl^- distribution in mouse astrocytes. It was found that the Cl^- content at steady state was 158 nmol/mg protein or about 25 to 30 mM. Since the membrane potential is about −75 to −80 mV, one has to conclude that Cl^- is not passively distributed but actively accumulated in astrocytes in such a way that its equilibrium potential is about −40 mV. When the cells are treated with furosemide, the K^+ content and the membrane potential were unaffected. However, the cells lost Cl^- resulting in a new Cl^- content of 68 nmol/mg protein. This amounts to a concentration of about 10 to 12 mM. This new concentration would be compatible with a equilibrium distribution of Cl^-, and with a Cl^- equilibrium potential that is similar to the membrane potential. Thus, one can conclude that the furosemide-sensitive carrier is responsible for active accumulation of Cl^- in astrocytes. Hoppe and Kettenmann (1989a) found similar results for cultured oligodendrocytes: Bumetanide resulted in a passive distribution of Cl^-.

Involvement in Potassium Accumulation

The involvement of a $Na^+/K^+/Cl^-$ carrier in the clearance of excess K^+ in the extracellular space was investigated by Walz and Hinks (1985, 1986) and Walz and Mukerji (1988). The studies focused on changes in the net content of K^+ in mouse astrocytes rather than the unidirectional K^+ influx. The cells were equilibrated at 3 mM K^+ and then exposed to 12 mM K^+. The cells increased their K^+ content by 390 nmol/mg protein or 63% within 50 s following the increase of external K^+. Ouabain, the Na^+-K^+ adenosine triphosphatase (ATPase) inhibitor, inhibited 240 nmol/mg of this net uptake. The same amount, 240 nmol/mg, was inhibited by furosemide application alone. Obviously, there is an overlap of the amount inhibited by ouabain and furosemide. Part of the uptake by one transport system is inhibited by the inhibition of the other system. A similar observation was made by Tas et al. (1986) for unidirectional K^+ fluxes of mouse astrocytes.

The furosemide-sensitive part of the net K^+ uptake was absent during Cl^- removal and reduced to about one-third in low-Na^+ solutions. This is a clear sign that furosemide-sensitive K^+ uptake is coupled to Cl^- and Na^+ fluxes; a mechanism which is similar to the one in rat astrocytes.

The water content of the mouse astrocytes increased by 27% during the 50 seconds following an increase of extracellular K^+ from 3 to 12 mM. Furosemide treatment alone did not change the water content of the astrocytes. However, in furosemide-treated cells that were exposed to 12 mM K^+, there was no swelling. Exposure to 12 mM K^+ in Cl^--free conditions did not produce a significant swelling.

In another set of experiments, the Na^+ gradient of the cells was changed by preincubation of the cells with zero K^+ solution. This treatement leads to a loss of intracellular K^+ and its replacement by Na^+ ions. In this way, the normal Na^+ content of the mouse astrocytes, about 200 nmol/mg protein, could be raised to 900 nmol/mg. Thus, the inward driving force for Na^+ could be abolished. If such cells, which were preincubated in zero K^+ and were now Na^+ loaded, were exposed to 12 mM K^+, there was a considerable net uptake of K^+ (400 nmol/mg) within the 1st min of exposure to 12 mM K^+. However, furosemide treatment had no effect on this net uptake, suggesting that a furosemide-sensitive or $Na^+/K^+/Cl^-$-mediated transport component does not contribute to this K^+ uptake, since the main driving force, the Na^+ inward gradient, was abolished. Thus, apart from the presence of Cl^- ions, the carrier needs an inward Na^+ driving force to function properly in its role during K^+ net uptake.

If the external K^+ was raised from 12 to 60 mM K^+, a net K^+ uptake of about 700 nmol/mg protein occurred within 1 minute. This amounts to a doubling of the K^+ content. The furosemide-sensitive component of this net uptake was minimal: 50 nmol/mg. However, the major part of this net uptake at these high, pathological K^+ concentrations was still inhibited by Cl^- removal, but only if Cl^- was replaced by glucuronate and not if replaced by isethionate. This clearly signals the participation of large conductance anion channels, which are permeable to many anions and which are activated only by large depolarizations. The driving force of the Na^+ gradient during the exposure to 60 mM K^+, when the cells depolarize from −85 to −10 mV, is greatly reduced. Thus, it is not surprising that under these conditions the inward movement of ions via the $Na^+/K^+/Cl^-$ carrier is largely dysfunctional and

replaced by passive Boyle and Conway mediated forces.

A Transmembrane Sodium Cycle

The previous observations, namely, a Cl^- and Na^+ dependence of the furosemide-sensitive K^+ net uptake, the overlap of the ouabain- and furosemide-sensitive components, and the dependency on an inward driving force for Na^+, all can be explained by a model of interdependency of the $Na^+/K^+/Cl^-$ carrier with the Na^+/K^+-ATPase. In this model, a coupling of both carriers via the intracellular Na^+ concentration results in a recycling of the Na^+ ion across the membrane. The cycle is illustrated in Figure 13-4. It involves a Na^+/K^+-ATPase that is stimulated by a high external K^+ and high intracellular Na^+. Elevated external K^+ also stimulates the $Na^+/K^+/Cl^-$ carrier, transporting these ions inward, since the sum of all driving forces will point inward. As a result, Na^+ is cycled across the membrane, carried inward by the $Na^+/K^+/Cl^-$ carrier and returned by the Na^+/K^+-ATPase. The whole mechanism leads to intracellular KCl accumulation and inward movement of water to compensate for increased osmolarity. At higher, probably pathological, K^+ levels, the driving force for the $Na^+/K^+/Cl^-$ carrier will be small. Consequently, this mechanism will lose importance as external K^+ levels progress beyond 10 mM K^+.

OUTLOOK

The results and concepts presented in this chapter are based on the assumption that intracellular Cl^- and HCO_3^- are evenly distributed in the cells. Recently, Hara et al. (1992) used cultured rat hippocampal neurones with a Cl^--sensitive fluorescent dye. They found an uneven distribution in the following order: processess >> periphery > central region. They attributed this to the localized distribution of a Cl^- pump and the Na^+-K^+-Cl^- cotransport. Kimelberg and Bourke (1982) first speculated on asymmetric arrangements of different transport mechanisms of the astrocytic perineuronal and perivascular membranes. This would serve to secrete HCO_3^- into the perineuronal space and H^+ into the perivascular region. It is of interest that Newman (1991) localized the Na^+/HCO_3^- cotransporter in freshly dissociated Müller cells from salamander retina and found a preferential localization in the endfeet regions. One can expect that the future use of fluorescent dyes will bring new findings and concepts regarding asymmetric arrangements of transport processes that will revolutionize our present view of anion transport.

14 pH regulation

JOACHIM W. DEITMER

pH regulation in nervous systems is an essential homeostatic function of the cellular elements known as glial cells and neurons. This is mainly achieved by transport of acid-base equivalents across the cell membranes. Substances transported out of these cells may be accumulated in the narrow spaces between nerve and glial cells—the extracellular or interstitial spaces—the third compartment in nervous tissue besides the two cellular elements (see Chapter 26, this volume).

The regulation of pH by glial cells in nervous systems raises two fundamental questions: (1) What are the mechanisms of intraglial pH regulation; and (2) Are these mechanisms involved in controlling the pH in the extracellular space (ECS)? In order to evaluate the role of glial cells in the overall H^+ homeostasis in nervous tissue, the production of acid-base equivalents by neurons, and the pH changes in the extracellular space, must be taken into account. These are discussed here only insofar as they may affect intraglial pH; the reader is therefore referred to some excellent reviews of these issues (Roos and Boron, 1981; Nattie, 1983; Moody, 1984; Thomas, 1984; Nicholson et al., 1985; Chesler, 1990; Chesler and Kaila, 1992; Ranson, 1992).

pH changes in nervous systems may have some important consequences for glial cell functions. As discussed in other chapters of this volume, intraglial acidification may uncouple glial cells and change their input resistance electrically (Tang et al., 1985; Walz and Wuttke, 1989; Kettenmann et al., 1990; see Chapter 19, this volume) and may lead to cell swelling during lactacidosis (Kraig and Petito, 1989; Staub et al., 1990; see Chapter 61, this volume) or to other pathophysiological changes (Hansen, 1985; Siesjö, 1988; Kraig and Chesler, 1990; see Chapter 64, this volume).

ELECTROCHEMICAL H^+ GRADIENT

Most living cells studied so far maintain an alkaline intracellular pH (pH_i) with respect to the H^+ electrochemical equilibrium. Therefore, cells must *actively* control their pH_i, which means that acid equivalents must be extruded out of the cells against a H^+/OH^- electrochemical gradient. Since the production of H^+ exceeds the H^+ consumption in most metabolic processes (Hochachka and Mommsen, 1983), cells and tissues have to extrude acid constantly. In addition, any leak of acid-base equivalents across the cell membrane would lead to a flow of H^+ into, or OH^- and HCO_3^- out of, the cell down their electrochemical gradient, which must be compensated by active transport in the opposite direction.

The H^+ equilibrium potential, at which H^+/OH^- and HCO_3^- are passively distributed across the cell membrane, is given by the Nernst equation:

$$E_H = \frac{RT}{F} * \ln \frac{[H^+]_0}{[H^+]_i}, \qquad (1)$$

where $[H^+]_0$ and $[H^+]_i$ are the concentrations of intra- and extracellular H^+ concentration, R is the gas constant, T the absolute temperature, and F the Faraday constant. This can be rewritten as

$$E_H = 58.5 \text{ mV } (pH_i - pH_0), \qquad (2)$$

where pH_i is the intracellular, and pH_0 the external pH; T was assumed to be 295 K (22°C). Equation (2) predicts that at a pH_0 of 7.4 (40 nM H^+) and a pH_i of 7.1 (80 nM H^+), the distribution of H^+ achieves an equilibrium at a cell membrane potential of −18 mV. This is far more positive than the membrane voltage of most cells. Consequently, at potentials more negative than −18 mV, H^+ must be actively extruded, although the intracellular H^+ concentration is twice that of the external fluid. In the example given, H^+ efflux has to overcome an electrochemical gradient of 57 mV, equivalent to about 1 pH unit.

If a membrane potential of −75 mV is assumed, as is more typical for glial cells, a passive H^+ distribution at pH_0 7.4 would give a pH_i value of 6.1 (coincidentally the pK′ of carbonic acid). This, however, is far too acid for most living cells to survive for any length of time due to inhibition of major enzymes at this low pH. Hence active pH_i regulation in glial cells is essential and can be predicted from these theoretical considerations alone.

pH IN THE GLIAL MICROENVIRONMENT

The constant extrusion of acid equivalents out of the cells results in some accumulation of acid in the extracellular spaces, rendering it 0.1 to 0.3 pH units more acid than the blood, cerebrospinal fluid, or bulk solution, both in vertebrates (e.g., Cragg et al., 1977; Urbanics et al., 1978; Javaheri et al., 1983) and invertebrates (Voipio et al., 1991; Deitmer, 1992a; Rose and Deitmer, 1992). These acid equivalents can be transported as H^+/OH^- or HCO_3^-, or as carboxylic acids, such as lactic acid (Kraig et al., 1985; Nicholson et al., 1985; Walz and Mukerji, 1988). The more acid microenvironment also reduces the H^+ electrochemical gradient across the cell membranes by 0.1 to 0.3 pH units, corresponding to 6 to 18 mV.

A remarkable exception has recently been observed in the stomatogastric ganglion of the crab (*Crustacea*), where the pH in the extracellular spaces (pH_e) was more *alkaline* than in the bulk solution (Golowasch and Deitmer, 1993). It appears as though additional mechanisms of pH_e control operate in this ganglion known for its coordinated, rhythmical, neuronal activity (Selverston and Moulins, 1987).

The steady-state pH_e and the pH_e shifts are affected by inhibition of the carbonic anhydrase, as, for example, with acetazolamide or ethoxyzolamide (Thomas et al., 1991; Chen and Chesler, 1992; Deitmer, 1992a; Kaila et al., 1992; Rose, 1993). Glial cells have been reported to contain a major fraction of the carbonic anhydrase in nervous tissue (Giacobini, 1962; Sapirstein et al., 1984), although, from the changes in experimentally induced pH_e shifts produced by carbonic anhydrase inhibition, it is suggested that either there is a considerable amount of carbonic anhydrase also in the extracellular space (Chen and Chesler, 1992; Deitmer, 1992b; Kaila et al., 1992) or carbonic anhydrase is located in the cell membranes with access to both intra- and extracellular compartments (Wistrand, 1984).

Acid and alkaline transients of up to several tenths of a pH unit can be recorded in the extracellular space during neuronal activity (Kraig et al., 1983; Somjen, 1984; Endres et al., 1986; Krishtal et al., 1987; Ranson et al., 1987; Chesler and Chan, 1988; Chvatal et al., 1988; Jarolimek et al., 1989; Walz, 1989; Sykova and Svoboda, 1990; Jendelova and Sykova, 1991; Rose and Deitmer, 1992; Rose, 1993) or under pathophysiological conditions, such as anoxia or ischemia (Thorn and Heitmann, 1954; Crowell and Kaufmann, 1961; Kraig et al., 1985; Krnjevic and Walz, 1989; Katsura et al., 1992; Ransom and Philbin, 1992; Ransom et al., 1992), spreading depression (Mutsch and Hansen, 1984; Chesler and Kraig, 1989; Scheller et al., 1992), or epileptiform activity (Siesjö et al., 1985; Takizawa et al., 1991; Laxer et al., 1992; Martins da Silva and Deitmer, 1993). In the ischemic brain, lactic acid levels may rise dramatically, leading to a severe acidification in the extracellular space; this lactacidosis may lead to glial cell swelling, impairment of synaptic transmission, or even cell death (Lomneth et al., 1990; Staub et al., 1990; Walz and Harold, 1990; Nedergaard et al., 1991; Scheller et al., 1992). It has been suggested that glial cells may help to control pH_e by mechanisms that tend to damp large pH_e transients, and thereby play an important role in maintaining H^+ homeostasis in nervous tissue (Siesjö, 1985; Ransom et al., 1987; Woodbury et al., 1988; Jendelova and Sykova, 1991; Kaila et al., 1991; Deitmer, 1992a; Ransom, 1992; Rose and Deitmer, 1994). In a recent study it was suggested that the pH_i regulation of astrocytes derived from *jimpy* mice, which carry a genetic disorder of myelination, is indeed abnormal, and the steady-state pH_i is considerably higher than in normal astrocyte cultures (Knapp et al., 1993).

pH_e changes may well be physiologically important. The conductance and/or gating of many membrane channels and carriers may be modulated by pH_e. This has been shown for γ-aminobutyric acid (GABA) receptor channels (Kaila et al., 1990), for the *N*-methyl-D-aspartate (NMDA)-type glutamate receptor channel (Tang et al., 1990; Traynelis and Cull-Candy, 1990), and for Ca^{2+} channels (Konnerth et al., 1987; Jarolimek et al., 1990; Kovalchuk et al., 1990; Mironov and Lux, 1991). This, in turn, may have severe consequences for neuronal excitability and information processing in the nervous system.

There is also evidence that pH_e changes not only modify neuronal ion channels, but also channels in the glial membrane. In glial cells of an oligodendrocyte lineage a rapid decrease of pH_0 elicited large Na^+ currents (Sontheimer et al., 1989). In cultured Schwann cells (Hoppe et al., 1989) and in leech neuropile glial cells (Munsch and Deitmer, 1991), the K^+ conductance was affected by pH.

MEASUREMENTS OF INTRAGLIAL pH

Direct intracellular pH measurements in glial cells were started only a few years ago (Chesler and Kraig, 1987; Deitmer and Schlue, 1987), much later than in neurons (Thomas, 1974; Boron and DeWeer, 1976), which have been studied extensively with respect to their pH regulation for about 20 years. This is not only due to the lack of interest in glial cells as

compared to nerve cells for a long time, but also due to the difficulties identifying cells as *glial* cells within nervous tissue, and to record from these glial cells directly. Apart from the rising interest in glial cells in the last 10 years, new techniques for identifying glial cells and measuring intracellular pH have led to substantial progress in this field.

The most commonly used technique for measuring intraglial as well as interstitial pH has been pH-sensitive, neutral carrier microelectrodes (Ammann et al., 1981), which impale the cell and provide an "on-line" recording of pH_i. The development of ion-sensitive fluorescent dyes (Heiple and Taylor, 1982; Rink et al., 1982), has created another powerful method to monitor pH_i directly and continuously. While the use of pH-sensitive microelectrodes is an "invasive" technique, since the electrode has to impale the cell, pH-sensitive fluorescent dyes, such as BCECF (2',7'-(biscarboxyethyl)-5,6-carboxyfluorescein), can be loaded via their membrane-permeable acetoxymethyl ester (AM), which is cleaved off in the cell by intrinsic diesterases. In addition, pH-sensitive microelectrodes give point measurements of pH_i and are, due to their very high electrical input resistance, slow as compared to the fluorescent dyes, which are fast and can provide spatial information of intracellular H^+ distribution.

On the other hand, in a tissue, the acetoxymethyl ester derivative of the fluorescent dyes would unselectively diffuse into different types of cells, unless injected by a conventional or patch-clamp microelectrode into individual cells, which would render this method "invasive" as well. Then, using fluorescent dyes, the absolute pH_i values can only be determined by H^+/K^+-permeabilizing the cells at the end of an experiment (e.g., using nigericin). This may be less accurate than determining pH_i with a pH-sensitive microelectrode, and only reveals the absolute pH_i value *after* an experiment. Hence roughly speaking, pH-sensitive microelectrodes are preferable in cells $\geq$ 15 to 20 μm in intact tissue, while fluorescent dyes are likely to be used in very small cells and in cell cultures.

Other techniques to measure pH_i, such as the distribution of the weak acid DMO (5,5'-dimethyl-2,4-oxazolidine) (Waddell and Butler, 1959; Chow et al., 1991, 1992), or the phosphorus shift in nuclear magnetic resonance (NMR) (Moon and Richards, 1973; Laxer et al., 1992) are either very costly (NMR), or may be less direct and/or reliable.

pH_i has been determined in a variety of glial cell types. The steady-state pH_i values obtained in different glial cells, either in intact tissue or in culture, ranged between 6.68 and 7.6 (Table 14-1). In all

DMSO, 5,5'-dimethyl-2,4-oxazolidine; BCECF, 2',7'-(biscarboxyethyl)-5,6-carboxyfluorescein; AM, acetoxymethyl ester.

glial cells, where pH_i was measured in different buffer systems, pH_i was lower in HEPES-buffered salines (6.68 to 7.32; mean 7.04 ± 0.2) than in CO_2/HCO_3^- buffered salines (7.04 to 7.6; mean 7.22 ± 0.16), corresponding to an average H^+ concentration in glial cells of 91 nM and 60 nM, respectively. The H^+ equilibrium potentials calculated from these values and an extracellular pH of 7.4 are −21 mV and −11 mV, respectively (at room temperature). This indicates the importance of CO_2/HCO_3^- for the maintenance of the alkaline steady-state pH_i.

INTRAGLIAL BUFFERING POWER

The intrinsic, intraglial buffering power (β_i) has only been determined in some studies; it varied between 20 and 37.7 mM (Table 14-1). The value of β_i includes the cytoplasmic, physicochemical buffering as well as the organellar buffering power, measured as the "instantaneous" change in pH_i as response to the addition of strong acid or base, in the absence of CO_2/HCO_3^- (for a more elaborate description of buffering, see Roos and Boron, 1981; Boron, 1985; Szatkowski and Thomas, 1989).

The total intracellular buffering power (β_T) is the sum of the intrinsic buffering power, β_i, and the CO_2/HCO_3^--dependent buffering power, β_{CO_2}. The latter is negligible in the nominal absence of CO_2/HCO_3^-, but may add considerable intracellular buffer capacity in the presence of 2 to 5% CO_2/10 to 26 mM HCO_3^-. β_{CO_2} depends upon the concentration of CO_2 and pH_i, which determines the intracellular HCO_3^- concentration. The capacity of intracellular H^+ buffering by CO_2/HCO_3^- is matched by the amount of intracellular HCO_3^- used, and can be written as

$$\beta_{CO_2} = \frac{\Delta[HCO_3^-]_i}{\Delta pH_i}, \quad (3)$$

where $\Delta[HCO_3^-]_i$ is the change in intracellular HCO_3^- concentration, and $\Delta\ pH_i$ the change in pH_i. The $[HCO_3^-]_i$ can be calculated by the modified Henderson-Hasselbalch equation

$$[HCO_3^-]_i = 10^{(pH_i - pH_o)} * [HCO_3^-]_o, \quad (4)$$

where $[HCO_3^-]_o$ is the external HCO_3^- concentration. Thus, equation (3) yields in first approximation

$$\beta_{CO_2} = 2.3\ [HCO_3^-]_i. \quad (5)$$

For example, from a value of 7.2 for pH_i, measured in a saline buffered with 5% CO_2/24 mM HCO_3^- at pH 7.4, the $[HCO_3^-]_i$ can be calculated to be 15.1 mM, which adds 34.8 mM buffering power to the cytoplasm. These are realistic values for glial cells, as well as for neurons and many other cell types; thus, the presence of CO_2/HCO_3^- can easily double or triple the buffering capacity provided by the intrinsic buffering power. In a cell with a steady-state pH_i of 7.2 in a CO_2/HCO_3^--buffered saline, the total buffering power may hence add up to 60 mM (assuming a β_i of 25 mM, and a β_{CO_2} of 35 mM, see above).

A pH_i value of 7.2 corresponds to a free H^+ concentration of 63 nM, and a buffering power of 60 mM predicts that the addition of 60 mM strong acid or base will change the pH by one unit. The ratio of free to "buffered" H^+ ($r_{H^+/H}$) is hence given by

$$r_{H^+/H} = \frac{10\ [H^+]_i}{\beta_T} \quad (6)$$

This means that, with the figures given above, for each free H^+ there are approximately 10^5 bound acid/base equivalents. If a cell is loaded with a large amount of acid, it will use most of its buffer capacity, so that a subsequent, equally large acid load will change pH_i much more. This is due to the fact that most H^+ binding sites were occupied by the first acid load. Consequently, the buffering power is greatly dependent on the actual pH_i value and upon the pK's of the intracellular buffering sites. Hence intracellular buffering is rapid and efficient on short term, but once saturated, it becomes inefficient.

Another way to cope with an acid load is to sequester acid equivalents into intracellular organelles, such as mitochondria and lysosomes ("organellar buffering power"). In most studies, this type of H^+ sequestering was not separated from the purely physicochemical buffering, which is why both are usually combined to the *intrinsic* buffering power. It is yet unclear, what role intracellular H^+ sequestration plays in controlling cytoplasmic pH in glial cells, but, in the long run, this organellar buffering power would approach saturation, unless acid equivalents are extruded from cells to maintain the cellular H^+ household.

Since the outward transport of acid equivalents or inward transport of base equivalents must be driven against the H^+/OH^- gradient in glial cells, as in most other cell types, they require some form of energy. These transport forms constitute the *active pH_i regulation* via membrane pumps and carriers.

MECHANISMS OF ACTIVE pH_i REGULATION

Like many other cell types, glial cells seem to use transport systems for their pH_i regulation. With most cells they share the use of a Na^+/H^+ exchanger and a Cl^-/HCO_3^- exchanger; with most *epithelial* cells they share a Na^+/HCO_3^- cotransporter, which

is absent in neurons and most nonepithelial cells. Recently, a bafilomycin-sensitive H^+ pump has been suggested in hippocampal astrocytes (Pappas and Ransom, 1993).

Little is known about the role of second messengers (see Chapter 34, this volume) on pH_i regulation in glial cells. The steady-state pH_i and the pH_i changes in leech glial cells were unaffected by intracellular Ca^{2+} transients evoked by membrane depolarization (Deitmer et al., 1993), suggesting that the homeostasis of H^+ and Ca^{2+} is not necessarily interrelated in these glial cells. There is evidence that neurotransmitters or hormones affect intraglial pH directly (Deitmer and Munsch, 1992) or by changing the glial membrane potential (see below) (Deitmer and Szatkowski, 1990) which may be mediated by intracellular messengers, such as cyclic nucleotides (J. W. Deitmer, unpublished observations). However, further studies are needed to elucidate the role of intracellular second messengers as modulators of intraglial pH.

Sodium/Hydrogen and Chloride/Bicarbonate Exchangers

Evidence for a Na^+/H^+ exchanger has been found in various glial cell types, as in cultured astrocytes (Kimelberg et al., 1979; Chow et al., 1991; Mellergard and Siesjö, 1991; Boyarski et al., 1993; Shrode and Putnam, 1994), in leech neuropile and connective glial cells (Deitmer and Schlue, 1987; Szatkowski and Schlue, 1992), in optic nerve astrocytes (Astion et al., 1989), in cultured oligodendrocytes (Kettenmann and Schlue, 1988), in rat Schwann cells (Nakhoul et al., 1994), and in glial or glioma cell lines (Benos and Sapirstein, 1983; Jean et al., 1986; Jacubovicz et al., 1987; Shrode and Putnam, 1994). The main criteria for the presence of a Na^+/H^+ exchanger, which drives H^+ out of the cells by using the energy of the Na^+ gradient with a stoichiometry of 1:1, are the following: (1) pH_i recovery from an acid load occurs in CO_2/HCO_3^--free saline; (2) pH_i recovery is dependent on external Na^+ and a large inwardly directed Na^+ gradient, and (3) independent of anions, such as Cl^- and HCO_3^-; and (4) the sensitivity of pH_i recovery to the K^+-sparing diuretic amiloride (Benos, 1982).

Cl^-/HCO_3^- exchange across glial cell membranes, either Na^+-independent or Na^+-dependent, has been reported for cultured astrocytes (Bourke et al., 1978; Kimelberg et al., 1979; Kimelberg, 1981), for cultured oligodendrocytes (Kettenmann and Schlue, 1988), and for leech glial cells (Deitmer and Schlue, 1987; Szatkowski and Schlue, 1992). This exchanger is identified by its dependence on Cl^- and HCO_3^-, and can be inhibited by SITS and/or DIDS, stilbene derivatives, which are known to inhibit anion carriers in cell membranes (Cabantchik and Rothstein, 1972). It may be inferred by analogy from studies on other cell types that the Na^+-independent Cl^-/HCO_3^- exchanger primarily *extrudes* HCO_3^-, and thereby helps to recover pH_i following an alkaline load (Thomas, 1977; Vaughan-Jones, 1979; Simchowitz and Roos, 1985).

The evidence for a Na^+-dependent Cl^-/HCO_3^- exchanger is based on pH_i recovery from an acid load, which shows similar properties as the Na^+-*independent* Cl^-/HCO_3^- exchanger, with the difference that it is dependent on the presence of external Na^+ and that it usually transports base equivalents *into* the cells. However, it is uncertain, whether Na^+ is actually transported by this carrier, and further characterization of this transport mechanism is needed to evaluate its role in intraglial pH regulation.

Both classical transporters for pH_i regulation, the Na^+/H^+ exchanger and Cl^-/HCO_3^- exchanger, although clearly identified in glial cells, have not been investigated in as great detail in glial cells as in some other cell types (see Wieth et al., 1982; Grinstein and Rothstein, 1986). This may also be the result of the apparent dominance of the Na^+-HCO_3^- cotransporter for intraglial pH regulation as found in a variety of glial cells. The impact of the presence of CO_2/HCO_3^- on pH_i regulation from an acid load in leech neuropile glial cells is shown in Figure 14-1. Recordings from different cells using the same protocol are shown, one with a double-barreled pH-sensitive microelectrode (Figure 14-1A), and one using the wavelength ratio 440 nm:495 nm of a cell filled with the fluorescent pH-sensitive dye BCECF (Figure 14-1B). The maximum rate of recovery from an intracellular acidification induced by an ammonium prepulse (see Roos and Boron, 1981) was five to ten times greater in the presence of 5% CO_2/24 mM HCO_3^- than in the nominal absence of CO_2/HCO_3^-. This is largely due to activation of an inwardly directed Na^+-HCO_3^- cotransport in these cells by the addition of CO_2/HCO_3^-, which also hyperpolarized the glial membrane (Figure 14-1) due to the electrogenic nature of the Na^+-HCO_3^- cotransporter.

Sodium-Bicarbonate Cotransporter

First evidence for a Na^+-HCO_3^- cotransporter in glial cells was found in the giant neuropile glial cells of the leech (Deitmer and Schlue, 1987, 1989), in astrocytes in the optic nerve of the mudpuppy *Necturus* (Astion and Orkand, 1988; Astion et al., 1989)

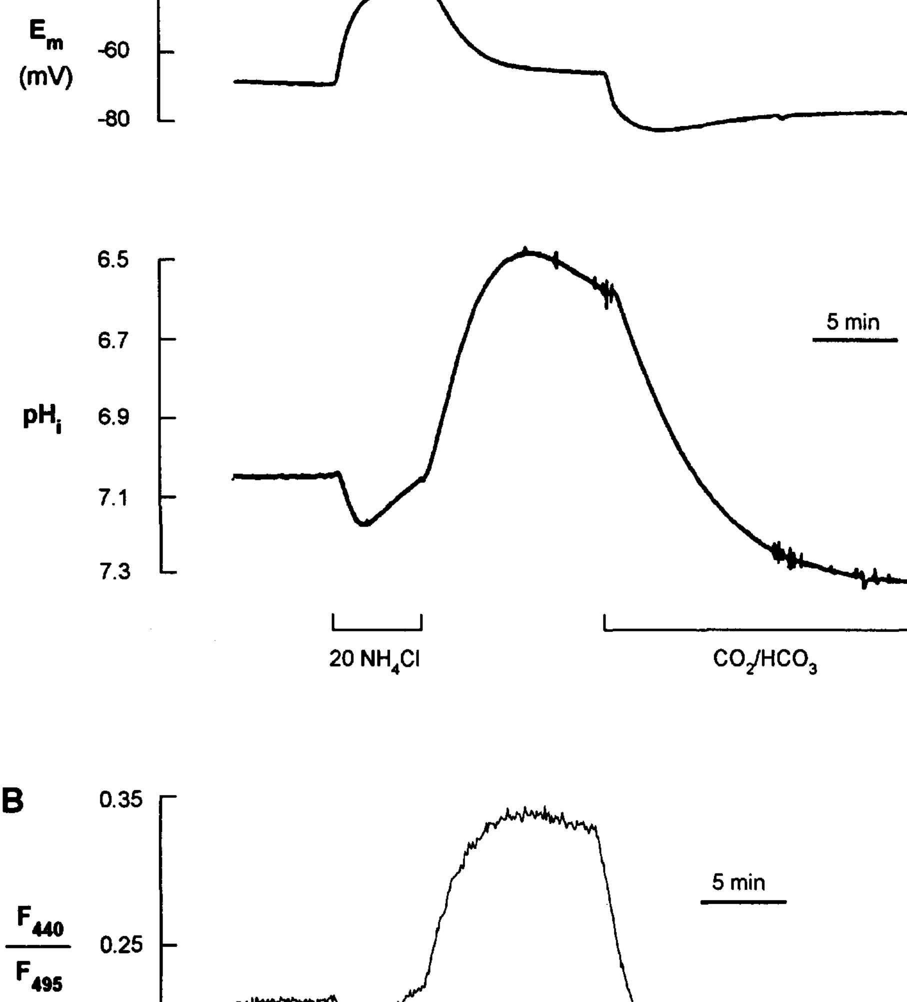

FIG. 14-1. (A) Intracellular recording of membrane potential (E_m, *upper trace*) and pH (pH_i, *lower trace*) in a leech neuropile glial cell using a double-barreled pH-sensitive microelectrode. After the application of ammonium (20 NH_4 Cl), the cell acidified. The recovery of pH_i in CO_2/HCO_3^--free, HEPES-buffered saline was slow, its maximum rate was 0.025 pH units/min. Following the addition of 5% CO_2/24 mM HCO_3^-, the pH_i recovery accelerated considerably; its maximum rate increased to 0.125 pH units/min. Note that the steady-state pH_i leveled at a more alkaline value in the presence of CO_2/HCO_3^-. (B) The same protocol was carried out in another neuropile glial cell using BCECF to measure intracellular pH, indicated by the fluorescence ratio 440 nm:495 nm (F440/F495), showing an even more dramatic change in pH_i recovery following the addition of CO_2/HCO_3^- [Figure B: from W. Nett and J. W. Deitmer, unpublished data.]

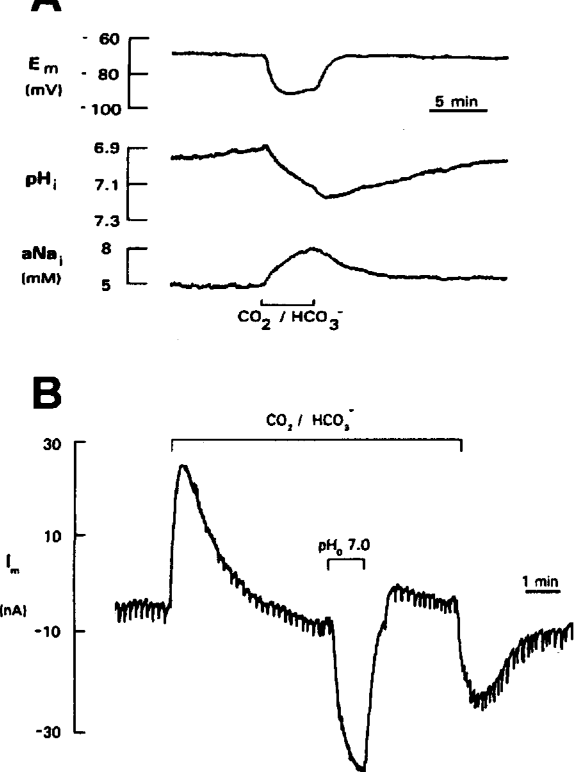
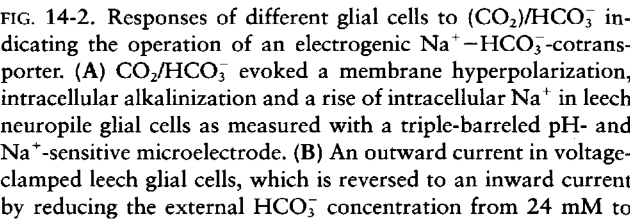
and in cultured mouse oligodendrocytes (Kettenmann and Schlue, 1988). In addition, a Na^+-HCO_3^- cotransporter was found in freshly dissociated Müller glial cells of the salamander retina (Newman, 1991; Newman and Astion, 1991), in cultured mouse astrocytes (Chow et al., 1991), and in leech connective glial cells (Szatkowski and Schlue, 1992). We have recently obtained evidence for an electrogenic Na^+-HCO_3^- cotransport in rat cerebellar astrocytes in culture, measuring a Cl^--independent and HCO_3^--dependent change in pH_i, and a Na^+- and HCO_3^--dependent current (Brune et al., 1994); similar results were reported for primary rat astrocytes (Shrode and Putnam, 1994).

In most of these studies, the Na^+-HCO_3^- cotransporter was detected during addition or removal of CO_2/HCO_3^-; addition of CO_2/HCO_3^- resulted in an intracellular alkaline shift, while removal of CO_2/HCO_3^- reversed this pH_i change (Figure 14-2A). Simultaneously, the glial membrane hyperpolarized and depolarized, respectively, during these buffer changes.

Since the CO_2/HCO_3^--dependent pH_i shifts and membrane potential changes were dependent upon the presence of external Na^+, but not on external or intracellular Cl^-, it was concluded that the underlying process might be an electrogenic Na^+-HCO_3^- cotransporter, similar in nature to that first described in proximal tubule cells of the salamander kidney (Boron and Boulpaep, 1983), and then in





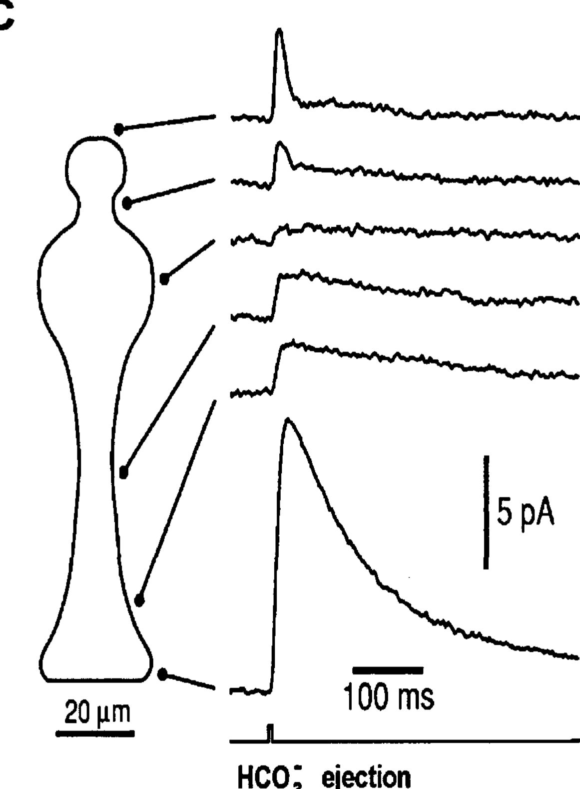


FIG. 14-2. Responses of different glial cells to $(CO_2)/HCO_3^-$ indicating the operation of an electrogenic $Na^+-HCO_3^-$-cotransporter. (A) CO_2/HCO_3^- evoked a membrane hyperpolarization, intracellular alkalinization and a rise of intracellular Na^+ in leech neuropile glial cells as measured with a triple-barreled pH- and Na^+-sensitive microelectrode. (B) An outward current in voltage-clamped leech glial cells, which is reversed to an inward current by reducing the external HCO_3^- concentration from 24 mM to 10 mM (pH_o 7.0) or by removal of CO_2/HCO_3^-. (C) Ejection of HCO_3^- from a pipette onto different regions of a salamander retinal Müller glial cell elicited outward currents of different amplitude, suggesting inhomogeneous distribution of electrogenic $Na^+-HCO_3^-$ cotransporter sites with preferential localization at the glial cell endfoot. [Figures A and B: from J. W. Deitmer, T. Munsch, M. Reusch, and H. P. Schneider, unpublished data; Figure C: from Newman (1991), with permission.]

many other epithelial cells (for references see Boron and Boulpaep, 1989). Indeed, there was a reversible rise in intracellular Na^+ during the exposure to CO_2/HCO_3^- (Figure 14-2A; see also Deitmer and Schlue, 1989; Deitmer, 1992b). In the absence of external Na^+, addition of CO_2/HCO_3^- neither produced the intracellular alkalinization nor a membrane hyperpolarization or outward current in leech glial cells (Munsch and Deitmer, 1994) and in rat astrocytes (Brune et al., 1994), indicating that there is no detectable HCO_3^- conductance in these glial cells.

In voltage-clamp, the addition of CO_2/HCO_3^- produced an outward current; subsequent reduction of the external pH by reducing the HCO_3^- concentration evoked an inward current (Figure 14-2B), consistent with an inward going electrogenic Na^+-HCO_3^- cotransport upon addition of CO_2/HCO_3^-, and a reversed, outward going cotransporter upon reduction of pH_o (and $[HCO_3^-]_o$) (Deitmer, 1991; Munsch and Deitmer, 1994; Brune et al., 1994).

As in epithelial cells, the Na^+-HCO_3^- cotransporter in glial cells could be inhibited by stilbene derivatives, such as DIDS, SITS, or DNDS, but was unaffected by amiloride. In retinal Müller glia, the DNDS-sensitive, Na^+- and HCO_3^--dependent current showed an inhomogeneous distribution (Newman, 1991) (Figure 14-2C), suggesting a higher density of Na^+-HCO_3^- cotransporter molecules in the glia endfoot than in the rest of the cell membrane. It could be shown in retinal glial cells that this HCO_3^--dependent current was directly dependent on the Na^+ gradient (Newman, 1991). It will be interesting to elucidate the function of this glial Na^+-HCO_3^- cotransporter in the retina, in particular as this cotransporter has also been found in retinal pigment epithelium (Hughes et al., 1989; La Cour, 1989).

The rate of pH_i change in leech glial cells was directly dependent on the extra- and intracellular HCO_3^- concentrations (Deitmer, 1991). The cotransporter could be reversed in leech glial cells (Deitmer and Szatkowski, 1990; Deitmer, 1991; Munsch and Deitmer, 1994) and in retinal Müller glial cells

(Newman, 1991; Newman and Astion, 1991), that is, operating inwardly *and* outwardly, depending on the thermodynamic conditions (Figure 14-2A, B). The stoichiometry reported for these two types of glial cells, however, was different. A stoichiometry of $2HCO_3^-$:$1Na^+$ was determined from the Na^+ and HCO_3^- gradients across the cell membrane of leech neuropile glial cells, as measured with ion-sensitive microelectrodes (Deitmer and Schlue, 1989; Deitmer, 1992b) and from the current reversal potential of −74 mV in a two-microelectrode voltage clamp (Munsch and Deitmer, 1994). In retinal Müller glial cells a stoichiometry of $3HCO_3^-$:$1Na^+$ was measured by means of the current reversal potential near −25 mV using the whole-cell patch-clamp technique. Since the stoichiometry is of crucial importance for the functional significance of such an electrogenic Na^+-HCO_3^- cotransporter, because it determines the *direction* of the transport, it should be considered in more detail.

With the intracellular Na^+ and HCO_3^- (pH) measured, the equilibrium potential (or reversal potential) of the Na^+-HCO_3^- cotransporter, E_{NaHCO_3}, is given by (see Boron and Boulpaep, 1983; Deitmer and Schlue, 1989)

$$E_{NaHCO_3} = \frac{RT}{(n-1)\cdot F} \ln \frac{[Na^+]_o\,[HCO_3^-]_o^n}{[Na^+]_i\,[HCO_3^-]_i^n}, \qquad (7)$$

where n is the HCO_3^-:Na^+ stoichiometry, and R, T, and F have their usual meanings. Assuming a stoichiometry of $n = 2$, the E_{NaHCO_3}, where no net transport is mediated by the carrier, was −74 mV in leech neuropile glial cells, at pH_i of 7.25 (17 mM HCO_3^-) and pH_o of 7.4 (5% CO_2/24 mM HCO_3^-), 10 mM free intracellular Na^+ concentration and 90 mM external Na^+ (Deitmer, 1992b). This corresponds well with the membrane resting potential (−73 mV) and the reversal of the Na^+-, HCO_3^--dependent current in voltage clamp (−74 mV) (Munsch and Deitmer, 1994). If a stoichiometry of $n = 3$ is assumed, E_{NaHCO_3} would be −41 mV under these conditions, which means that the cotransporter would extrude Na^+-HCO_3^- at potentials negative to −41 mV, and stimulation of the cotransporter would normally *depolarize* the cell membrane, until the membrane potential equals the equilibrium potential of the Na^+-HCO_3^- cotransporter. Measurements of membrane potential changes, voltage-clamp currents, and intracellular ion activities, however, clearly indicates a stoichiometry of $n = 2$.

This stoichiometry implies that the cotransporter operates near its equilibrium at normal resting membrane potential. Depolarization stimulates inward-going, and hyperpolarization stimulates outward-going Na^+-HCO_3^- cotransport accompanied by intracellular alkalinization and acidification, and by outward and inward currents, respectively (Figure 14-3A), rendering intraglial pH and acid-base flux across the glial membrane very sensitive to membrane potential changes (Deitmer and Szatkowski, 1990; Munsch and Deitmer, 1994; Deitmer and Schneider, 1995). The maximal rates of pH_i change, converted to base (HCO_3^-) flux and the peak currents were directly and similarly correlated with membrane voltage (Figure 14-3B).

The reversal potential of the cotransporter in retinal Müller glial cells, determined in whole-cell clamp using the HCO_3^--dependent, DNDS-sensitive current, gave a stoichiometry of 3 HCO_3^-:1 Na^+ (Newman, 1991; Newman and Astion, 1991), as found in most epithelial cells (Boron and Boulpaep, 1989). This suggests that, at rest, a sustained outwardly directed cotransporter operates in these cells, acidifying the cytosol, and providing base equivalents to the retinal extracellular space.

With a stoichiometry of $1Na^+$:$3HCO_3^-$, the outwardly directed HCO_3^- gradient and the negative membrane potential would overcome the large inwardly directed Na^+ gradient and extrude Na^+ and HCO_3^-. Hence stimulation of the cotransporter would acidify the cytoplasm and depolarize the cell membrane. Only large depolarizations of the cell membrane well beyond −40 mV (−25 mV) would reverse the cotransport to an inwardly directed mode.

In an electroneutral cotransport, Na^+ and HCO_3^- would be carried into the cell due to the large inwardly directed Na^+ gradient, which is about twice that of the HCO_3^- outward gradient. An electroneutral Na^+-HCO_3^- was reported for cultured oligodendrocytes (Kettenmann and Schlue, 1988), where it thus would function as a mechanism to *increase* pH_i.

EFFECT OF NEURONAL ACTIVITY AND NEUROTRANSMITTERS ON INTRAGLIAL pH

It is of great interest, how far and by what mechanisms the steady-state pH_i and the pH_i regulating processes in glial cells are affected by electrical activity of, and neurotransmitter release by, neurons. In concert with other ions and metabolites, H^+ changes in glial cells, neurons and in the ECS may be part of the neuronal-glial cross talk.

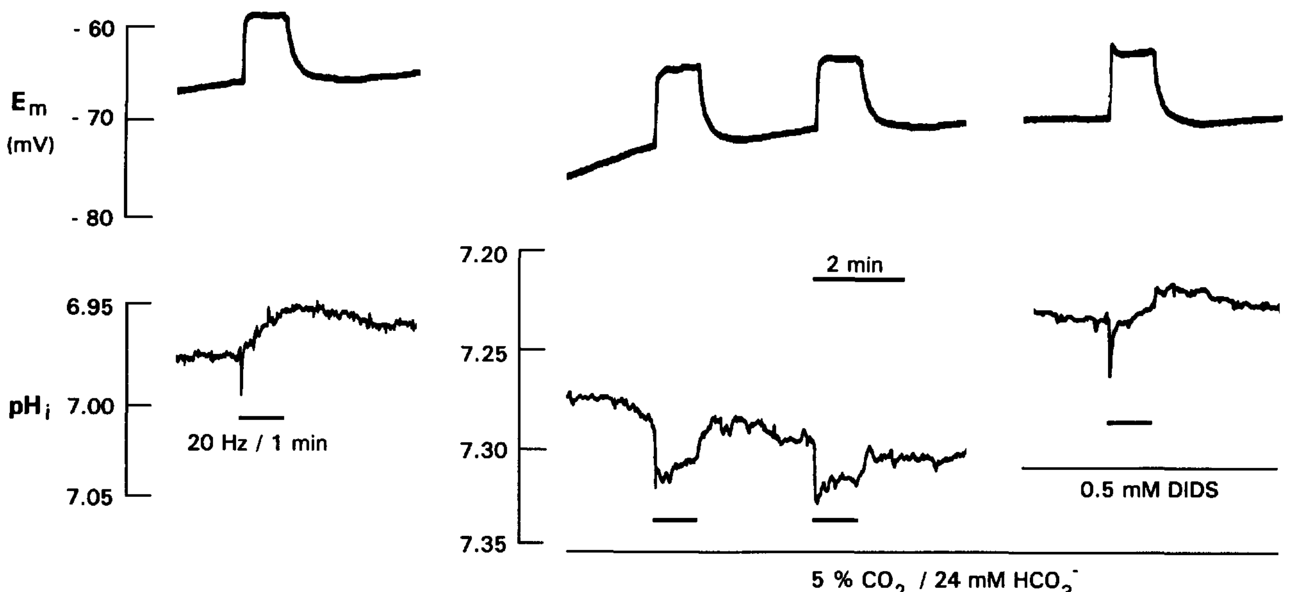

FIG. 14-4. Stimulation-induced changes in membrane potential (E_m, *upper traces*) and pH (pH_i, *lower traces*) of a leech neuropile glial cell in nominal CO_2/HCO_3^--free, HEPES-buffered saline (left panel) and in the presence of CO_2/HCO_3^- (*middle and right panels*). The stimulation-induced alkalinization in CO_2/HCO_3^--buffered saline was reversed by DIDS (diisothiocyanatostilbene-2,2′-disulfonic acid), which blocks the $Na^+-HCO_3^-$ cotransporter in this cell. Stimulation occurred by applying a voltage to a side nerve of a leech segmental ganglion via suction electrode. [From Rose (1993), with permission.]

Neuronal Stimulation

Stimulation of the cortical surface of rat brain (20 Hz) produced a rapid, sustained membrane depolarization (20 mV) and an intracellular alkalinization of about 0.2 pH units in astrocytes in the frontal cortex (Chesler and Kraig, 1987, 1989). In leech neuropile glial cells stimulation of a side nerve caused a similar depolarization, and a rapid intracellular alkalinization, which was substantially reduced by DIDS or in the absence of CO_2/HCO_3^- (Figure 14-4) (Rose and Deitmer, 1992; Rose, 1993). It has been suggested that the glial depolarization is presumably due to the accumulation of extracellular K^+, released by the neurons during activity, while the depolarization might be the cause for the intracellular alkalinization. This membrane depolarization would stimulate inwardly directed, electrogenic Na^+-HCO_3^- cotransport and hence alkalinize the glial cytoplasm. This DIDS-sensitive uptake of base equivalents (Figure 14-4) significantly reduces the stimulation-induced alkaline transient in the extracellular space (Rose, 1993; Rose and Deitmer, 1994) and supports the hypothesis that glial acid-base regulation helps to control extracellular pH (Deitmer, 1992a; Ransom, 1992).

At the end of the stimulation, the glial membrane repolarized, which was accompanied by a recovery of pH_i. Sometimes, the membrane slightly hyperpolarized, and the pH_i decreased transiently. This is in accordance with the dependence of pH_i on the membrane potential due to the activity of the electrogenic Na^+-HCO_3^- cotransporter in the glial membrane (Deitmer and Szatkowski, 1990; Munsch and Deitmer, 1994; Deitmer and Schneider, 1995). Membrane hyperpolarization would drive the cotransporter in the outward direction, acidifying the glial cytoplasm and providing base equivalents to the ECS (Deitmer, 1991, 1992a; Rose and Deitmer, 1994).

Action of Neurotransmitters

Glial cells have a large number of neurotransmitter receptors, which might be, similar to neurons, cou-

FIG. 14-3. (A) Recording of intracellular pH (*lower traces*) and membrane current (*middle traces, superimposed*) during slow 5-minute voltage steps between −70 and −100 mV (*upper trace*) in the absence and in the presence (*) of $CO_2-HCO_3^-$. Note the additional, largely transient, extra currents and the increased pH_i changes in the saline containing 5% CO_2−24 mM HCO_3^- (B) Maximum rate of acid-base flux (*left*) and peak current (*right*) plotted versus the membrane voltage during 5-minute voltage-clamp steps (for the experiment shown in Figure A) in the presence (○, △) and absence (●, ▲) of 5% CO_2−24 mM HCO_3^-. [From Munsch and Deitmer (1944), with permission.]

pled to ion channels (see Chapters 21 and 22, this volume). Transmitters and their agonists may lead to changes of intraglial pH, for example, due to some permeability of these channels to H^+/OH^- or HCO_3^-. Therefore, intraglial pH changes observed during neuronal stimulation may also be due to the action of neurotransmitters, which are released during neuronal stimulation. However, so far intraglial *alkalinizations* have mainly been reported during neuronal stimulation (see above), and intraglial *acidifications* following the action of neurotransmitters.

A fall of pH_i in cultured rat astrocytes was measured following the activation of $GABA_A$ receptors (Kaila et al., 1991). Since $GABA_A$ receptor channels are not only permeable to Cl^-, but also to HCO_3^- (Kaila and Voipio, 1987; Voipio et al., 1991), HCO_3^- moves down its electrochemical gradient through these channels out of the cell, thereby acidifying the cell interior, and alkalinizing the extracellular space (Chen and Chesler, 1992; Kaila et al., 1992). Indeed, a fall in pH_i mediated by $GABA_A$ receptor channels was monitored also in rat astrocytes (Kaila et al., 1991), and in leech neuropile glial cells (J. W. Deitmer, unpublished observations). The pH_o changes were affected by $GABA_A$ receptor blockers and by inhibition of carbonic anhydrase, which catalyzes the dissociation of carbonic acid. Local ejection of GABA into the CA1 region of rat hippocampus caused a HCO_3^--dependent, picrotoxin-sensitive, rapid extracellular alkaline shift, similar as can be observed during cortical stimulation (Chen and Chesler, 1990, 1992). Interestingly, the stimulation-induced extracellular alkaline transient was blocked by picrotoxin, an inhibitor of $GABA_A$ receptor channels, in rat hippocampal slices (Kaila et al., 1992), but significantly increased in the leech central nervous system (Rose, 1993).

Glutamate and acetylcholine cause an acid shift in glial cells (Figure 14-5). Activation of the kainate-type glutamate receptor produced a fall of 0.2–0.3 pH units in leech glial cells (Deitmer and Munsch, 1992), suggesting that this receptor channel is not only permeable to Na^+ and Ca^{2+} (Deitmer and Munsch, 1992; Müller et al., 1992), but also to H^+. Figure 14-5A shows the membrane potential change and intracellular acidification of a leech neuropile glial cell upon application of the glutamate agonist kainate. This acidification was not dependent upon HCO_3^-, and the cell recovered from this acidosis within minutes. Carbachol, an agonist of acetylcholine receptors, elicited a smaller membrane depolarization and an intracellular acidification of 0.1 to 0.2 pH units (Figure 14-5B).

The intraglial acidification produced by acetylcholine, and its agonists carbachol and nicotine, ranged between 0.09 and 0.33 pH units in CO_2/HCO_3^--free saline, and could be reduced by external Zn^{2+} (2 mM) (Ballanyi and Schlue, 1989; Schneider, 1990). Again, H^+ permeation through acetylcholine-gated channels in the glial membrane would be the simplest explanation for this pH_i decrease, although this has to be confirmed by further studies. In the presence of CO_2/HCO_3^- a multiphasic pH_i was evoked by carbachol, whereby the intracellular acidification was followed and partly masked by an alkalinization (Schneider, 1990; J. W. Deitmer, unpublished observations). The latter may be due to the concomittant membrane depolarization, stimulating inward-going Na^+-HCO_3^- cotransport.

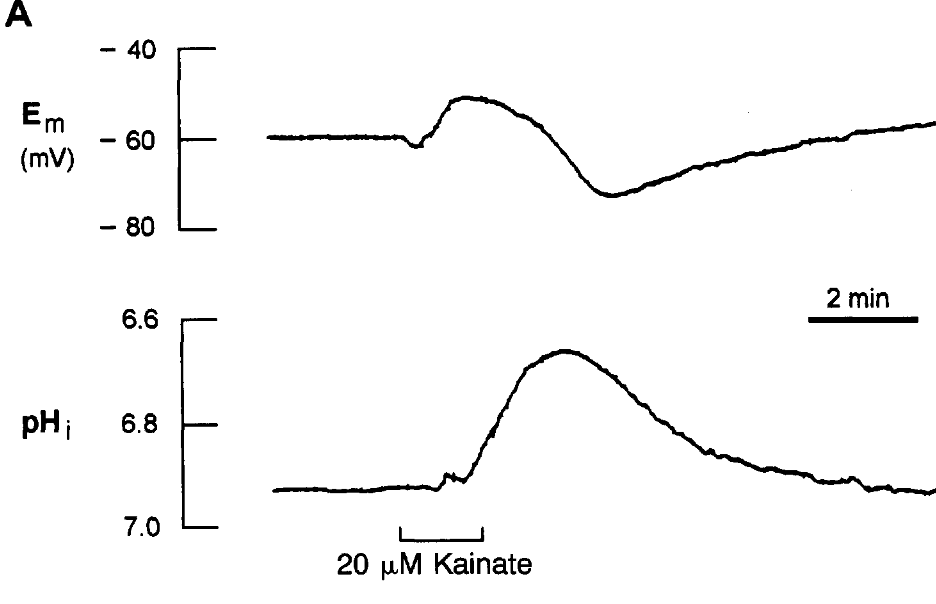
Local ejection of glutamate into the hippocampus produced an extracellular alkaline shift, similar to that following stimulation of the Schaffer collaterals (Chen and Chesler, 1992). While inhibition of carbonic anhydrase abolished the GABA-induced extracellular alkaline shift, it enhanced the alkaline shifts evoked by glutamate and Schaffer collaterals, indicating that the latter arises through a HCO_3^--independent mechanism, while the GABA-evoked alkalinization is consistent with a HCO_3^- efflux through $GABA_A$-receptor channels.

In the leech central nervous system, kainate and carbachol induced biphasic pH shifts in the extracellular space, that is, a brief alkalinization followed by a large acidification, while GABA and serotonin (5-HT) had little or no effect on the extracellular pH (Rose, 1993).

Although the impact of neurotransmitter-induced intraglial pH changes have only begun to be understood, it becomes clear that these processes may well take part in the modulation of pH in the extracellular space, particularly in the vicinity of synapses, where transmitters may transiently accumulate. This may be of special functional significance, since the conductance and/or gating of neurotransmitter- and voltage-activated neuronal and glial channels can be directly modulated by H^+ (see Chapter 2).

CONCLUSIONS

Since the first intracellular pH measurements in glial cells *in vivo* only some years ago, it has become clear now that glial cells possess a variety of processes that modulate intraglial pH as well as the pH in the extracellular space. Figure 14-6 summarizes the main membrane processes relevant for perturbing and regulating intraglial pH. The largest pH_i changes appear to be contributed by the neurotransmitters and the reversible, electrogenic Na^+-HCO_3^- cotrans-



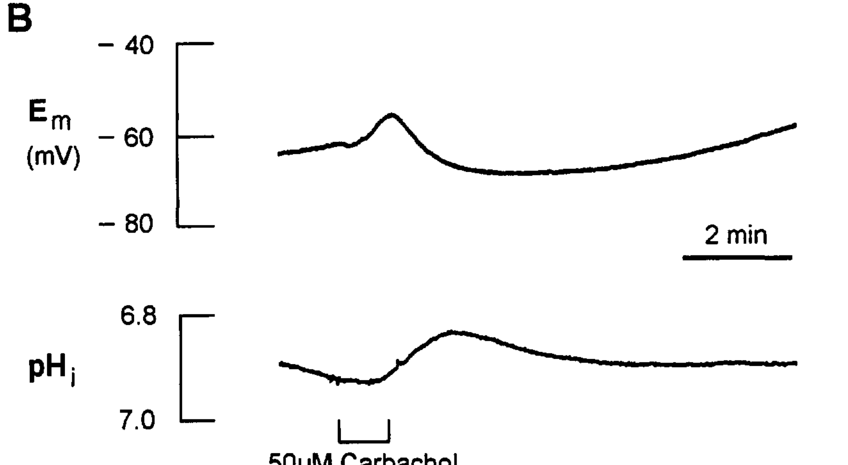


FIG. 14-5. (A) The effect of the glutamate receptor agonist kainate, and (B) the acetylcholine receptor agonist carbachol on membrane potential (E_m) and intracellular pH (pH_i) of a leech neuropile glial cell. [From J. W. Deitmer, unpublished data.]

porter. With respect to the action of neurotransmitters on pH_i, glial cells appear to resemble neurons, while the glial Na^+-HCO_3^- cotransporter is reminiscent of epithelial cells.

The action of neuronal electrical activity, neurotransmitters and the H^+/HCO_3^--transporting carriers in the cell membranes produce pH shifts in neurons, extracellular space, and glial cells. It seems often necessary to monitor pH in *all three compartments* in order to understand the mechanisms of the acid and alkaline transients. We have begun to learn some of the mechanisms of these diverse and multiphasic pH changes. It is clear that glial cells regulate their pH_i, and make a significant contribution to the pH_o shifts, which feed back on neuronal and glial cell functions. For nearly all events related to pH changes in nervous tissue, the presence of HCO_3^- has a great impact; HCO_3^- determines the buffering power to a large extent, it enables HCO_3^- flux through $GABA_A$ receptor channels and thereby modifies the inhibitory synaptic potentials, and HCO_3^- is the substrate for the powerful glial electrogenic Na^+-HCO_3^- cotransporter. The maintenance of pH in neurons, glial cells and extracellular space, and the modulation of pH_o, plays an important and diverse role in the functioning of nervous systems; glial cells may take the part of a H^+ caretaker, similar as has been postulated for K^+, and some neurotransmitters and metabolites.

The experimental work, as far as carried out in our laboratory, has been supported by grants from the Deutsche Forschungsgemeinschaft.

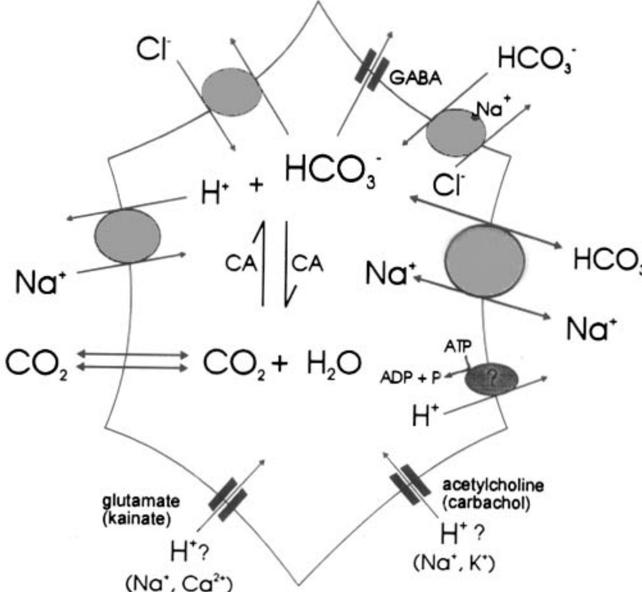

FIG. 14-6. Schematic summary of membrane channels and carriers relevant for pH_i in a hypothetical glial cell. The carbonic anhydrase (*CA*) catalyzes a fast equilibrium between $H^+ + HCO_3^-$ and $CO_2 + H_2O$, to which the cell membrane is permeable. An ATP-driven proton pump has been suggested, and the H^+ permeability of glutamate and acetylcholine receptor channels still needs to be shown more directly (hence marked with *question mark*). The Na^+-dependent $Cl^- - HCO_3^-$ exchange may actually transport Na^+. The steady-state pH_i, at least in some glial cell types, appears to be dominated by the electrogenic $Na^+ - HCO_3^-$ cotransport, which may operate as a voltage-dependent pH_i clamp.

15 Transport of neuroactive amino acids in astrocytes

ARNE SCHOUSBOE AND NIELS WESTERGAARD

All animal cells express a number of relatively specific transport systems for amino acids that are classified on the basis of Na^+ dependency and amino acid specificity (cf. Christensen, 1990). These transport systems are also found in brain cells (Sershen and Lajtha, 1979). Specific high-affinity transport systems for the neuroactive amino acids glutamate, aspartate, GABA, taurine, and glycine are present in the brain in addition to the above-mentioned amino transport systems (Sershen and Lajtha, 1979). The availability of preparations of neurons and astrocytes in primary cultures during recent years has made it possible to investigate in detail the properties of these amino acid transport systems at the cellular level (cf. Schousboe, 1982b). This chapter focuses on the properties of the astrocytic transport systems for the above-mentioned amino acids, but, for the sake of comparison, neuronal amino acid transport systems are also described.

EXCITATORY AMINO ACIDS

Glutamate and Aspartate

Kinetics and Substrate Specificity. The kinetic properties of glutamate uptake have been studied in a large variety of preparations of glial cells including bulk-prepared cells, cell lines, and primary cultures (cf. Schousboe, 1981, 1982b). Table 15-1 summarizes K_m and V_{max} values for cultured astrocytes and neurons. It can be seen that the glial uptake system exhibits high affinity for glutamate; if V_{max} values are compared with those determined in different neuronal preparations, including glutamatergic neurons, the conclusion is that glial cells and, in particular, astrocytes are more efficient than neurons with regard to glutamate transport (Hertz, 1979; Schousboe, 1981, 1982b; Hösli et al., 1986; Schousboe et al., 1988; Erecinska and Silver, 1990).

Detailed mutual inhibition and uptake studies of acidic amino acids with either carboxylic or sulfonic/sulfinic acidic groups have shown that in astrocytes L-glutamate, L-aspartate, cysteic sulfinate (CSA), and cysteate (CA) are likely to share the same carrier (Table 15-2). Apart from the finding that D-aspartate is a mixed competitive and noncompetitive inhibitor of L-glutamate uptake (Table 15-2), this amino acid also seems to share this carrier. In this context, it is interesting that the higher homologues of CSA and CA, homocysteic sulfinate (HCSA) and homocysteate (HCA) are not transported by the same carrier. This is, however, in line with the prediction (Schousboe et al., 1988) that in order for an acidic amino acid to bind efficiently to the carrier the two acidic groups must be close to each other. Molecular modeling of these molecules clearly illustrates this notion (Griffiths et al., 1989). Similar uptake and inhibition studies have been performed in cultured neurons and synaptosomes (Drejer et al., 1983b; Griffiths et al., 1989; Grieve et al., 1991; Rauen et al., 1992) and essentially the same pattern was observed. It should be noted, however, that in neurons and synaptosomes, D-aspartate is a competitive inhibitor of L-glutamate uptake (Drejer et al., 1982; Rauen et al., 1992), whereas as seen in Table 15-2 and confirmed in a recent study by Rauen et al., (1992), D-aspartate is either a noncompetitive or a mixed competitive/noncompetitive inhibitor in astrocytes. That the neuronal and astrocytic glutamate carriers may be kinetically different is also suggested by the following observations. β-Methylene-aspartic acid (β-MA) inhibits astrocytic D-aspartate or L-glutamate uptake noncompetitively (Bender et al., 1989; Dunlop et al., 1992) but inhibits neuronal D-aspartate uptake competitively (Dunlop et al., 1992). Moreover, L-*trans*-pyrrolidine-2,4-dicarboxylate (L-*trans*-PDC) has been shown to be a more potent inhibitor of synaptosomal glutamate uptake than of glial glutamate uptake when its efficacy was compared at a fixed glutamate concentration (Rauen et al., 1992). Surprisingly, however, when a kinetic analysis was performed, the K_i value for L-*trans*-PDC was higher in synaptosomes than in astrocytes, indicating that the compound is a more efficient inhibitor of astrocytic glutamate uptake (Rauen et al., 1992). In any event,

there is reason to believe that the neuronal and astrocytic glutamate carriers may differ from each other, a notion borne out by recent cloning and immunohistochemical studies (Danbolt et al., 1992; Pines et al., 1992; Storck et al., 1992) as discussed below.

Ionic Requirements. Many studies have shown that glutamate uptake into astrocytes is sodium-dependent (cf. Schousboe, 1981, 1982b; Schousboe et al., 1977b, 1988; Erecińska and Silver, 1990) and the K_m for Na^+ is low (Schousboe et al., 1977b, 1988). There have been conflicting reports of the coupling ratio be-

Astrocytes were cultured as described by Hertz et al. (1982, 1989b) and the kinetic analysis of uptake and inhibition performed as detailed by Drejer et al. (1983b), Griffiths et al. (1989), and Grieve et al. (1991), which also contain the original data.

Glu, glutamate; Asp, aspartate; CA, cysteic acid; CSA, cysteine sulfinic acid; HCA, homocysteic acid; HCSA, homocysteine sulfinic acid.

tween Na^+ and glutamate (cf. Erecińska and Silver, 1990), but this value is probably greater than unity, as indicated by studies of influx of $^{22}Na^+$ and glutamate simultaneously (Stallcup et al., 1979; Kimelberg et al., 1989). In addition to the Na^+-dependent high-affinity glutamate-uptake system, a Cl^--dependent component may be present in astrocytes, but it seems only to account for a minor fraction of the total glutamate uptake (Pin et al., 1984; Waniewski and Martin, 1986; Bridges et al., 1987; Flott and Seifert, 1991). These findings regarding sodium and chloride dependency of the astrocytic glutamate carrier are largely in line with what has been reported for neuronal glutamate uptake (cf. Schousboe et al., 1988; Erecińska and Silver, 1990). The glial glutamate carrier has also been shown to depend on K^+ and pH or bicarbonate (Sarantis and Attwell, 1990; Barbour et al., 1991; Bouvier et al., 1992). According to the model of Bouvier et al. (1992), glutamate is cotransported with two sodium ions, while one K^+ and one OH^- (or HCO_3^-) are countertransported, making the carrier highly electrogenic. Depolarization accordingly will reverse the carrier, leading to a large efflux of glutamate (Sarantis and Attwell, 1990; Szatkowski et al., 1990).

Molecular Characterization and Cloning. Recent cloning studies have established the existence of at least three glutamate carriers with different degrees of homology in the amino acid sequences (Kanai and Hediger, 1992; Pines et al., 1992; Storck et al., 1992). The carrier cloned by Pines et al. (1992) has been shown by immunohistochemistry to be exclusively located in astrocytes (Danbolt et al., 1992). The carrier cloned by Kanai and Hediger (1992) from rabbit small intestine was shown by *in situ* hybridization studies to be also present in the brain (Kanai and Hediger, 1992). Its cellular localization was, however, not firmly established, but it appears to be present in neurons. When expressed in *Xenopus* oocytes it was shown to have the same basic properties with regard to substrate specificity as described above (Kanai and Hediger, 1992). Also the transporter cloned from the brain exhibits the kinetic pattern of the astrocytic glutamate carrier when incorporated into liposomes subsequent to extraction from HeLa cells transfected with the cDNA (Pines et al., 1992). Based on hydropathy analysis these two carriers (Pines et al., 1992; Kanai and Hediger, 1992) have been proposed to have different numbers of membrane-spanning domains, reflecting different amino acid sequences. Thus the glial glutamate carrier has been proposed to consist of eight putative membrane-spanning domains (Pines et al., 1992), whereas the carrier cloned from the rabbit intestine supposedly has ten such domains (Kanai and Hediger, 1992). Further cloning studies are likely to reveal additional subtypes of glutamate transporters in analogy to what has been demonstrated for glutamate receptors (cf. Gasic and Heinemann, 1991), although the heterogeneity of the carrier family may not turn out to be as complex as the heterogeneity of the receptor family.

Factors Regulating Carrier Expression. It is well documented by a number of studies (Schousboe and Divac, 1979; Drejer et al., 1982; Hansson, 1983, 1986) that astrocytic glutamate uptake differs with regard to capacity among astrocytes from different brain regions. It was originally suggested that such differences in the efficacy of glutamate uptake could be related to the role of astrocytes as the primary site for inactivation of glutamatergic activity as the uptake of glutamate was particularly pronounced in astrocytes originating from brain areas with a pronounced glutamatergic activity (Schousboe and Divac, 1979). It has subsequently been demonstrated that neuronally released macromolecular substances, presumably proteins, have the ability to increase the functional activity of glutamate carriers in astrocytes (Drejer et al., 1983a; Schousboe et al., 1986b). Future studies should be aimed at a better understanding of such processes as they could represent an important regulatory mechanism for astrocytic amino acid uptake (see Chapter 48, this volume).

INHIBITORY AMINO ACIDS

Gamma-Aminobutyric Acid

Kinetics and Substrate Specificity. Table 15-3 summarizes K_m and V_{max} values for GABA uptake into a variety of preparations of glial cells. K_m values vary in the range 1 to 50 μM, but clearly glial cells possess a high-affinity transport system for GABA. Comparison of GABA uptake into glial cells and neurons (cf. Schousboe 1981, 1982b; Hösli et al., 1986) shows that neurons have a higher capacity for GABA uptake than astrocytes. According to Hertz and Schousboe (1987) about 20% of GABA released from GABAergic neurons will be taken up into adjacent astrocytes, whereas the remaining 80% may be taken up into the nerve endings and hence will be available for release as a neurotransmitter. The demonstration that GABA analogues (cf. Figure 15-1 and Table 15-4), which preferentially inhibit glial GABA uptake, act as anticonvulsants (Horton et al., 1979; Frey et al., 1979; Krogsgaard-Larsen et al., 1981; Meldrum et al., 1982; Croucher et al., 1983; Wood et al., 1983; Schousboe et al., 1986a; Gon-

Cells were cultured as described by Hertz et al. (1982, 1989a, 1989b) and the kinetic analyses of uptake and inhibition of GABA and its analogues were performed as described in the original publications (Schousboe et al., 1981, 1990a, 1991a; Larsson et al. 1981, 1983, 1985, 1988).

DPB, diphenylbutenyl derivatives of the parent compound; THPO, (4,5,6,7-tetrahydroisoxazolo[4,5-*c*]pyridin-3-ol); THAO, (4,5,6,7-tetrahydroisoxazolo[4,5-*c*]azepin-3-ol); ACHC, *cis*-3-Aminocyclohexane carboxylic acid; C, competitive inhibition; N, noncompetitive inhibition; n.d., Not determined.

salves et al., 1989a, 1989b; White et al., 1993) indicates that uptake of GABA into astrocytes is of physiological and functional importance (cf. Schousboe et al., 1991a; Chapter 48, this volume). This has also been demonstrated in cocultures of GABAergic neurons and astrocytes in which administration of THPO (4,5,6,7-tetrahydroisoxazolo[4,5-*c*]pyridin-3-ol) led to an enhanced depolarization coupled release of GABA (Westergaard et al., 1992).

Glial GABA uptake traditionally has been claimed to be selectively inhibited by β-alanine, and this amino acid has been widely used as a marker of glial GABA uptake (Iversen and Kelly, 1975; Schon and Kelly, 1975). Recent studies of the kinetics of uptake of GABA, β-alanine and taurine, as well as their mutual inhibition in synaptosomes, neurons, and astrocytes (Larsson et al., 1986b; Debler and Lajtha, 1987) have, however, questioned this dogma. As can be seen from Table 15-5, β-alanine in both cell types shares a transporter with taurine, which is distinct from that of GABA. This is apparent from the competitive nature of inhibition of taurine uptake by β-alanine and the noncompetitive nature of the corresponding inhibition of GABA uptake. On this basis, it may not be advisable to use β-alanine as the only experimental tool to identify and selectively investigate glial GABA transport sites.

Ionic Requirements. GABA transport in astrocytes is dependent on external sodium (Schousboe et al.,

TABLE 15-5. *Mutual Inhibition by GABA, Taurine, and β-Alanine of the Transport of the Same Amino Acids in Neurons and Astrocytes*

Amino Acid as Substrate	Amino Acid as Inhibitor					
	Neurons			Astrocytes		
	GABA	Taurine	β-Alanine	GABA	Taurine	β-Alanine
GABA	25[a]	15,500(N)	1,666(N)	31[a]	1,000[c]	843(N)

Mouse cerebral cortex neurons and astrocytes were cultured as detailed by Hertz et al. (1982, 1989a, 1989b) and uptake experiments performed as described by Larsson et al. (1986a), which also contain the original data.

[a] K_m (μM) values for uptake of the respective amino acid.

[b] The values indicated with (N) or (C) represent K_i (μM) values for the inhibition; N, noncompetitive inhibition by the amino acid acting as an inhibitor; C, competitive inhibition by the amino acid acting as an inhibitor.

[c] The type of inhibition is not clarified (A. Schousboe, unpublished observations).

1977a; Larsson et al., 1986a). It is interesting that the coupling ratio between Na^+ and GABA changes from unity to a value of 2 or more when astrocytes mature and differentiate in culture (Larsson et al., 1986a). Whether the same is true for astrocytes *in vivo* is not known, but if this is the case it has important functional implications for clearance of GABA from the extracellular environment. As the efficiency of the transport system greatly increases with an increase in the sodium coupling ratio (Martin, 1976; Schousboe, 1981), extracellular GABA levels are likely to be higher during early development of the central nervous system than at later more differentiated stages. Since GABA acts as a neuronal differentiation signal during early development (Redburn and Schousboe, 1987; Meier et al., 1991) such a relative inefficiency of cellular GABA uptake may be quite important during a period where overall GABA concentrations are low but where the extracellular availability of GABA may be of importance for normal neuronal development.

In addition to its dependence on sodium, GABA uptake is also chloride-dependent (Kanner, 1978) which contrasts with glutamate uptake (cf. above discussion). On the other hand, glial GABA uptake is not dependent on the presence of potassium (Hertz et al., 1978b) but is inhibited by depolarizing concentrations of potassium (Schousboe et al., 1977a). This is due to the fact that when GABA is cotransported with sodium the efficiency of the transport system decreases greatly with an increase in the membrane potential, that is, a depolarization (Martin, 1976; Schousboe, 1981).

Molecular Characterization and Cloning. A GABA transporter (GAT-1) was first cloned and sequenced by Kanner and coworkers (Guastella et al., 1990) and it was established that it belongs to a superfamily of neurotransmitter transporters, including those for dopamine and serotonin. They are characterized by 12 putative membrane-spanning domains (Guastella et al., 1990), a characteristic also proposed for the intestinal glutamate transporter but not for the glial glutamate transporter (cf. above discussion). Since the first cloning of a GABA transporter by Guastella et al. (1990), two other GABA-transporter clones (GAT-2 and GAT-3) have been reported (Borden et al., 1992). The cellular location of these transporters has so far not been firmly established, but the kinetic diversity of GABA-transporters described above clearly is supported by the results of the cloning experiments. These experiments do not, however, clarify the pharmacological distinction between neuronal and glial GABA uptake (Table 15-4), and it is not clear whether the GAT-1, GAT-2, and GAT-3 clones represent neuronal or glial GABA carriers (Borden et al., 1992).

Factors Regulating Carrier Expression. In analogy with what was reported for glial glutamate uptake (cf. above discussion), glial GABA uptake can be enhanced by neuronally released substances (Drejer et al., 1983a). Recently, a 30 kD glycoprotein has been purified from conditioned media from cultured cerebellar granule cells, which induces GABA carriers in astrocytes (Nissen et al., 1992) and hence is named GABA carrier-inducing protein (GABA-CIP). The inducing effect is indicated by the observation that the increase in V_{max} for GABA uptake seen after exposure of the cells to GABA-CIP could be prevented by the protein synthesis blocker actinomycin D (Nissen et al., 1992). This may represent an as yet unknown mechanism by which neurons may be able to regulate astrocytic functions pertinent to maintenance of neuronal signaling pathways.

Glycine

Kinetics and Ionic Requirements. High-affinity glycine uptake has been demonstrated in a number of neural preparations (cf. Schousboe, 1982b; Hösli et al., 1986). Detailed kinetic studies concerning astrocytic glycine uptake are, however, scarce but such an uptake system has been convincingly demonstrated (Wilkin et al., 1981; Hannuniemi and Oja, 1981; Zafra and Giménez, 1986; Reynolds and Herschkowitz, 1986; Hösli et al., 1986; Ottersen et al., 1987; Holopainen and Kontro, 1989). The kinetic characteristic of astroglial glycine uptake is similar to that found in neurons (Holopainen and Kontro, 1989). Inhibition studies have shown that glycine uptake is mediated by a specific carrier, which is different from those transporting other inhibitory neurotransmitter amino acids (Holopainen and Kontro, 1989). The glial glycine uptake is strictly Na^+-dependent and it is also Cl^--dependent, although this dependency is less pronounced than that for Na^+ (Holopainen and Kontro, 1989).

Taurine

Kinetics and Substrate Specificity. Since the first reports on astrocytic high-affinity taurine uptake (Borg et al., 1976; Schousboe et al., 1976), taurine uptake has been studied in a number of glial cell preparations and kinetic constants for glial taurine uptake have been summarized in Table 15-6. Also neurons of different phenotypes express a high-affinity carrier for taurine (Holopainen et al., 1983, 1984, 1987; Larsson et al., 1986b; Abraham and Schousboe, 1989;

[a]Per mg DNA

Schousboe et al., 1991b). Taurine uptake is inhibited by structural analogues of taurine (Holopainen, 1984; Holopainen et al., 1983, 1984, 1987) most notably by β-alanine (Table 15-5) and guanidino ethane sulfonic acid (GES). The actions of the latter compound have recently been extensively reviewed (Huxtable, 1992). It is important to stress that taurine and GABA, which share certain inhibitory properties (cf. Hösli and Hösli, 1978; Huxtable, 1989), do not share the same carrier, as evidenced by the kinetic studies summarized in Table 15-5.

Ionic Requirements. Studies of taurine uptake in astrocytes have shown that the carrier is dependent on both Na^+ and Cl^- for its action (Schousboe et al., 1976; Holopainen et al., 1987; Holopainen, 1988). The sodium dependency is also confirmed by the observation that taurine uptake into C-6 glioma cells is inhibited by ouabain (Sieghardt and Karobath, 1976). The coupling ratio between sodium and taurine has been reported to be close to unity (Schousboe, 1982a), but recent experiments (A. Schousboe, unpublished observations) have indicated that this coupling ratio is closer to 2 in more differentiated astrocytes. In analogy to what has been found for GABA uptake, taurine uptake is inhibited by high concentrations of K^+ due to the depolarization of the cells (Schousboe et al., 1976).

Molecular Characterization and Cloning. Recent cloning studies (Liu et al., 1992; Smith et al., 1992) have shown that the taurine carrier from rat or mouse brain is structurally related to the GABA carrier, that is, the protein has 12 putative membrane-spanning segments. It should be noted, however, that the cDNAs for the GABA and taurine carriers only exhibit partial homology with about 60% nucleotide identity. The reconstituted carrier was inhibited by β-alanine, confirming kinetic studies on taurine transport in intact brain cells (cf. above discussion). These cloning studies have also underlined the conclusion from previous studies of the kinetic properties of GABA and taurine uptake (cf. above discussion) that these two amino acids are transported by distinctly different carriers.

Taurine Fluxes and Cell Swelling. It has recently been convincingly shown that astrocytic (and neuronal as well) cell swelling and the subsequent regulatory volume decrease (cf. Kimelberg and Ransom, 1986) is associated with a pronounced efflux of taurine and to a lesser extent of some other amino acids (Pasantes-Morales and Schousboe, 1988, 1989; Kimelberg et al., 1990; Martin et al., 1990; Pasantes-Morales et al., 1990; Schousboe et al., 1990b; Schousboe and Pasantes-Morales, 1992). Although this efflux of taurine does not appear to be mediated directly by

the taurine carrier (Sanchez-Olea et al., 1991, 1992; Schousboe et al., 1991b; Pasantes-Morales et al., 1993), the taurine carrier is of functional importance for this process to occur. The basis for this role of taurine in cell volume regulation is its high intracellular concentration, which is secured by the activity of the carrier (cf. Sanchez-Olea et al., 1991).

NEUROTRANSMITTER-RELATED AMINO ACIDS

Glutamine

Glial glutamine transport has been investigated in different preparations, including bulk-prepared cells and cultured astrocytes (Weiler et al., 1979; Schousboe et al., 1979; Ramaharobandro et al., 1982). Values for K_m and V_{max} vary considerably between these studies, but uptake rates calculated at an extracellular glutamine concentration of 100 μM are quite similar, being about 1 nmol × min^{-1} × mg^{-1} protein (Schousboe et al., 1988). By comparison, both GABAergic and glutamatergic neurons appear to have similar capacities for glutamine uptake as those reported for astrocytes (Schousboe et al., 1988). The substrate specificity of the glutamine carrier suggests that it may serve as a transporter for several amino acids such as alanine, leucine, and arginine (Christensen, 1990; Erecińska and Silver, 1990). There are only few studies available concerning the ionic requirements for glutamine uptake. Neurons and synaptosomes exhibit Na^+ dependency (Ramaharobandro et al., 1982; Erecińska et al., 1990), but no consistent data showing sodium dependency seem available for glial glutamine uptake.

Arginine

Remarkably little is known about how L-arginine is transported into brain cells. Synaptosomes have been shown to transport arginine and to subsequently metabolize it into ornithine, which can function as a precursor for glutamate, GABA, and proline (Johnson and Roberts, 1984). Arginine has recently attracted considerable attention as a precursor for the highly diffusible molecule nitric oxide, which is likely to be involved in signal transduction in the central nervous system (Garthwaite, 1991; Snyder and Bredt, 1991). In the light of a possible important role of arginine transport for the regulation of synthesis of nitric oxide, studies have been performed to characterize the transport of arginine into cultured astrocytes (Wiesinger, 1992) and into cultured neurons (Westergaard et al., 1993a). The K_m values are around 50 to 100 μM and the uptake of arginine in the two cell types is largely sodium-independent but strongly inhibited by depolarizing concentrations of potassium. The pattern of inhibition by basic L-amino acids is consistent with a "y^+" transport system (Christensen, 1990). In the light of the importance of arginine as a precursor for nitric oxide, it is of interest that the two nitric oxide synthase inhibitors N^G-monomethyl-L-arginine and N^G-amino-L-arginine have been shown to be potent inhibitors of arginine uptake into cultured neurons (Westergaard et al., 1993a).

Alanine

Alanine uptake has been demonstrated in brain slices (Cohen and Lajtha, 1972; Sershen and Lajtha, 1979) and in nerve terminal-enriched material (Shank and Campbell, 1982) but very little is known about alanine uptake into cultured astrocytes and neurons. Recently, Westergaard et al. (1993b) have reported kinetic constants for alanine uptake in astrocytes (K_m ~ 450 μM; V_{max} 8 nmol × min^{-1} × mg^{-1}) and neurons (K_m ~ 275 μM; V_{max} 16 nmol × min^{-1} × mg^{-1}), indicating that alanine uptake is more efficient into neurons than into astrocytes. The uptake was dependent on sodium with a K_m value for sodium around 5 mM in both cell types. The observed inhibition by high concentrations of glycine, valine, and glutamine is compatible with the notion that the alanine carrier present in these cultured cells represents the sodium-dependent carrier for small neural amino acids (Christensen, 1990). In this context it should be noted that the preferential uptake of alanine into neurons supports the notion that alanine may play an important role as an amino group donor for biosynthesis of neurotransmitter glutamate from α-ketoglutarate (Peng et al., 1991; Hertz et al., 1992; Schousboe et al., 1992a, 1992b; Schousboe and Westergaard, 1993).

CONCLUDING REMARKS

It is clear that astrocytes express high-affinity carriers for the amino acids that are either neurotransmitters or neuromodulators in their own right or serve as precursors for these substances. Since astrocytes are in close anatomical contact with synapses, it is very likely that these cells serve important roles with regard to supply of transmitter precursors to neurons and with regard to inactivation of the neurotransmitter amino acids. This latter function appears to be of particular physiological importance in case of the excitatory amino acids glutamate and aspartate. Maintenance of a low extracellular concen-

tration of these amino acids (below 5 μM) appears to be of utmost importance for protection of neurons against cytotoxic actions of these amino acids (Nicholls and Attwell, 1990) and the highly efficient high-affinity glutamate-aspartate carrier in astrocytes is well suited to serve this purpose. Although astrocytic glutamate uptake is superior to that present in nerve cells, it should be emphasized that the neuronal glutamate uptake is in no way to be regarded as functionally unimportant. In glutamatergic neurons it may ensure that released glutamate can be taken up into the nerve ending and reutilized as a neurotransmitter. In this context it should be emphasized that, although glutamate can to some extent be reutilized as a neurotransmitter, a considerable drain from the neurotransmitter pool occurs. Therefore uptake of other precursors such as glutamine, alanine, and α-ketoglutarate is important (Hertz et al., 1992; Schousboe et al., 1992b; Schousboe and Westergaard, 1993). Since these metabolites are all primarily synthesized in astrocytes, these cells are of fundamental importance for supply of precursors for synthesis of neurotransmitter glutamate in neurons. In other types of neurons the uptake of glutamate could well be a mechanism by which the concentration of glutamate in the microenvironment of cells is kept at a low level. The reutilization of amino acid neurotransmitters by neurons appears to be a very important principle in the case of GABA. In this case astroglial GABA uptake may prevent reuse of released GABA, and hence partial inhibition of glial GABA uptake may enhance the inhibitory activity of GABAergic neurons and thereby prevent seizures.

The observation that astrocytes as well as neurons have a high-affinity uptake system for arginine is interesting, as arginine is the precursor to nitric oxide, an important signaling molecule in the brain (Snyder and Bredt, 1991). The finding that some of the inhibitors of nitric oxide synthase are potent inhibitors of the arginine transporter may point to the possibility of developing drugs affecting nitric oxide synthesis by acting as inhibitors of arginine uptake, which appears to be rate-limiting for nitric oxide synthesis (Westergaard et al., 1993a).

The expert secretarial assistance of Ms Hanne Danø is cordially acknowledged. Financial support from the Danish State Biotechnology Program (1991–95) as well as from the NOVO and Lundbeck Foundations is cordially acknowledged.

16 Na,K-ATPase and its isoforms

KATHLEEN J. SWEADNER

(Na^+ + K^+)-stimulated adenosine triphosphatase (Na,K-ATPase, or sodium pump) is a protein embedded in the plasma membrane. It catalyzes the active uptake of K^+ and extrusion of Na^+ at the expense of hydrolyzing ATP to ADP and P_i. This uphill transport establishes steep concentration gradients for the ions. The gradients are then harnessed by other proteins for a variety of essential functions, including electrical potential changes mediated by ion channels, the uptake of molecules like neurotransmitters, and the extrusion of Ca^{2+}. The Na,K-ATPase is phylogenetically ancient but is not found in protists or plants. Where it is found, it is always inhibitable by a class of natural toxins, the cardiac glycosides, such as digitalis and ouabain.

ENZYMATIC CHARACTERISTICS, AND THEIR IMPLICATIONS FOR FUNCTION IN GLIA

Active Na^+ and K^+ transport carried out by the Na,K-ATPase has certain basic characteristics in all well-studied cell types (Jørgensen, 1986). All cells require Na,K-ATPase activity to maintain their ion gradients. The amount of Na,K-ATPase activity found varies markedly, however, and typically reflects the ion flux work load. Astrocytes, like neurons, muscle, and transporting epithelia, have a relative abundance of the enzyme; fibroblasts and many other cell types have much less.

Hydrolysis of ATP by the Na,K-ATPase is accompanied by sequential protein conformation changes that translocate the ions (Jørgensen, 1986). Figure 16-1 shows a schematic diagram. Binding of Na^+ at the intracellular face accelerates the transfer of the terminal phosphate of ATP to an aspartate side chain in the active site, and this brings about a large conformation change that delivers Na^+ to the outside of the cell. Binding of K^+ then causes a conformation change that accelerates the hydrolysis of the covalently bound phosphate, and the K^+ is transported to the inside of the cell as the enzyme returns to its initial conformation. The principal enzyme conformations are known as E1 and E2; E1 is found in the presence of Na^+ and E2 in K^+, but the phosphorylated form of E2 (E2-P) is found in the presence of Na^+, Mg^{2+}, and ATP. The gene family of ion-transporting ATPases is sometimes referred to as the P-type ATPases (for their covalent phosphorylation at the active site) or the E1-E2 ATPases (for their characteristic conformation changes).

Although no crystal structure is available for the sodium pump, much is known about the enzymatic mechanism (Jørgensen and Andersen, 1988). Both Na^+ and K^+ can be demonstrated to be "occluded" at some stage of the turnover cycle: that is, caught within the membrane protein with no access to either side. The protein does not rotate within the membrane; instead ions are believed to move between membrane-spanning protein segments. These transmembrane segments may shift relative to one another, and they may rise or sink somewhat with respect to the plane of the membrane.

The whole turnover cycle is very slow compared to conductance through ion channels. When going at full speed, the enzyme will complete one turnover in 6 to 10 msec, moving $3Na^+$ in exchange for $2K^+$. The fact that one net positive charge is moved out of the cell makes the pump electrogenic. The cell compensates for the slowness of each Na,K-ATPase unit by making a lot of them. In excitable cells it is one of the most abundant plasma membrane proteins. Collectively, the pumps in a cell can make a direct contribution of 1 to 5 mV (hyperpolarization) to the membrane potential.

Affinities for the substrates (Na^+, K^+, and Mg·ATP) have been measured with purified enzyme (Jørgensen, 1986). A salient feature is that the affinities for all of the ligands are affected by the concentrations of the others and by the conformational state, leading to many apparent discrepancies in the literature. Nonetheless, it is reasonable to state that typical concentrations for half-maximal activation of ATPase activity are 5 to 10 mM for Na^+; 1 mM for K^+, and 0.3 mM for Mg·ATP. This means that extracellular K^+ (3.6 mM or more) and intracellular ATP (2 to 3 mM) are much less likely to be rate-limiting for enzyme activity than intracellular Na^+ (5 to 10 mM). In fact, there is much experimental evidence [mostly in transporting epithelia, liver, and cardiac

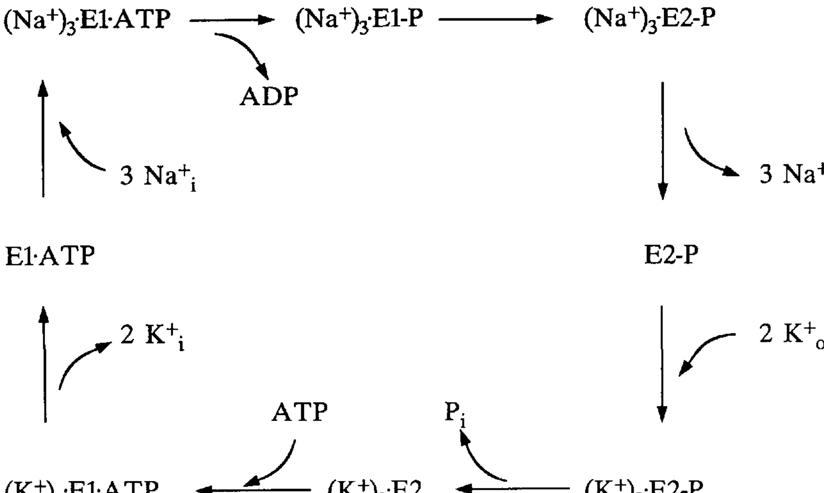

FIG. 16.1 Conformational changes of the Na,K-ATPase. This is a simplified scheme showing how the Na,K-ATPase couples the energy of ATP hydrolysis to the movement of ions across the membrane.

myocytes, but also in synaptosomes (Erecinska, 1989)] that elevation of intracellular Na^+ directly results in an increase in Na,K-ATPase activity. In measurements of pump current in intact cardiac cells, it has also been shown that affinities for extracellular K^+ (0.2 to 1.5 mM depending on conditions) are very similar to those measured with purified enzyme (Nakao and Gadsby, 1989).

Potassium ions are close to electrochemical equilibrium when the interior of the cell is negative, and so it does not cost the sodium pump very much thermodynamic energy to move K^+ from one side of the membrane to the other.* In contrast, Na^+ is far from its electrochemical equilibrium potential, since its diffusion into the cell is favored by both the concentration gradient and the voltage difference established by the open K^+ channels. This makes the active transport of Na^+ back out of the cell very energetically unfavorable. Na^+ transport should be less unfavorable during the transient depolarization of excitable cells. It has been demonstrated that the pump current (measured with whole-cell patch clamp recording) is actually voltage-dependent (De Weer et al., 1988). It is the translocation of Na^+, rather than K^+, that shows sensitivity to the membrane potential. The initial steps (the binding and occlusion of Na^+) are not very sensitive, but the release of Na^+ to the outside of the cell is (De Weer et al., 1988). In principle, if a hyperpolarized glial cell is depolarized by any means, one would predict that its Na,K-ATPase activity would increase even in the absence of changes in the saturation of its Na^+ and K^+ binding sites. The pump current in cardiac myocytes, for example, more than doubles between −85 mV and 0 mV (Figure 16-2) (Gadsby and Nakao, 1989).

Electrophysiological studies of pump activity have led to an explicit prediction about the structure of the enzyme. The Na,K-ATPase behaves quantitatively as if there were an "ion well," subject to membrane po-

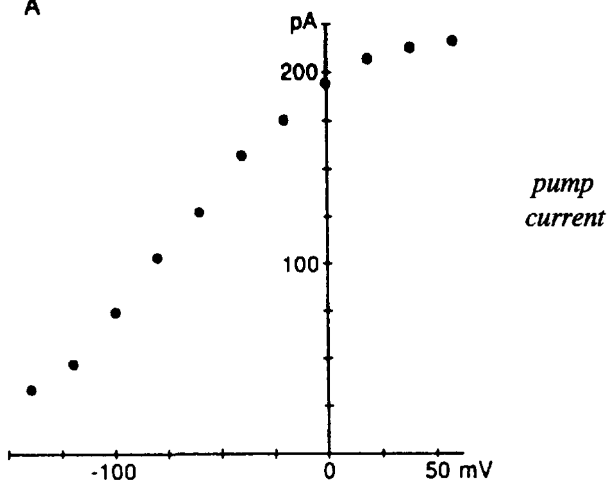

FIG. 16-2. Voltage-dependence of sodium pump current. Pump current was measured in cardiac myocytes using whole cell patch clamp. The current due to the Na,K-ATPase was assessed by subtracting values obtained with and without strophanthidin (a ouabain analogue). Conductance through various other pathways was minimized with TEA, Ba^{2+}, Cd^{2+}, and the removal of extracellular Ca^{2+}. Transmembrane voltage was changed in steps (millivolts; mV) and the resulting strophanthidin-sensitive current is plotted (picoamps; pA). For this experiment, intracellular (pipette) Na^+ was 50 mM, while extracellular Na^+ was 150 mM and extracellular K^+ was 5.4 mM. [From Gadsby and Nakao (1989), with permission.]

*The fundamental basis for electrical excitability is first, that gradients for Na^+ and K^+ are established across the membrane, and second, that a resting membrane potential is generated by opening K^+ channels, but not Na^+ channels. K^+ then diffuses down its concentration gradient (leaving its counterion behind) until the separation of charge produces enough of an electrical force to oppose further diffusion.

tential, within the protein but connected to the extracellular surface (Läuger, 1991a). Ions apparently move part of the way across the membrane between transmembrane segments in a narrow channel. This channel leads to a tighter region, deep within the protein, where ions are bound and conformation changes control ion translocation. Figure 16-3 illustrates this concept diagrammatically.

In summary, the properties of the prototypical sodium pump include (1) that intracellular Na^+, not extracellular K^+, is normally rate-limiting for turnover, and (2) that voltage dependence is a factor in cells with high and variable membrane potentials. Both of these enzymological features may affect how the Na,K-ATPase functions in glia.

DOES THE Na,K-ATPase MEDIATE POTASSIUM ION CLEARANCE?

As described in more detail in Chapter 31, astrocytes have an essential role in clearing the K^+ that is released from neurons into the extracellular cleft during activity. It has been proposed that the Na,K-ATPase directly takes up the K^+ (reviewed in Stahl, 1986; Sweadner, 1989; Reichenbach et al., 1992). This would be in contrast to K^+ uptake primarily by channels or carriers (refer to Chapters 11, 13, and 18), in which the Na,K-ATPase would play only a supporting role.

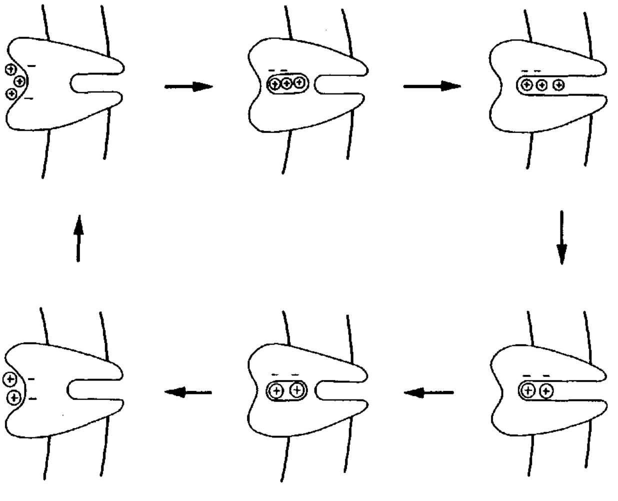

FIG. 16-3. An ion well within the Na,K-ATPase. Voltage-dependent properties of the Na,K-ATPase predict that ions must diffuse part way through the membrane in a pore in the protein, influenced by the membrane potential. The pore is presumably lined by transmembrane segments, and may be the site of cardiac glycoside binding. The intracellular surface is to the left and extracellular surface to the right. [From Läuger (1991b), with permission.]

There is a precedent for a role for the Na,K-ATPase in K^+ clearance elsewhere in the body (Moore, 1983). Serum K^+ levels would increase significantly after eating a meal if there were no mechanism for clearing the newly ingested K^+. The role of the Na,K-ATPase differs from its proposed role in glial-mediated K^+ clearance, however, because raised serum K^+ is not sufficient by itself to increase the activity of the pump. Instead, the signal is a hormone. Elevated serum K^+, like elevated glucose, stimulates the release of insulin from the β cells of the pancreas. Insulin then acts on skeletal muscle, liver, and fat to increase the activity of the Na,K-ATPase. The pump takes up the K^+ and stores it (predominantly in skeletal muscle) as a reservoir for later buffering of serum K^+ levels. Stimulation of ion transport is one of the most rapid of the many effects of insulin, but the mechanism is still debated (Guidotti, 1990). In liver and skeletal muscle, insulin increases intracellular Na^+ levels, thus activating the Na,K-ATPase by increasing the availability of the rate-limiting substrate inside the cell. In addition, insulin seems to increase Na,K-ATPase V_{max} by mechanisms that are not yet understood, possibly including recruitment of intracellular Na,K-ATPase pools to the plasma membrane.

Can the Na,K-ATPase mediate K^+ uptake in astrocytes directly in response to elevated extracellular levels? Its enzymatic properties must be considered. First, for an increase in extracellular K^+ to activate the Na,K-ATPase, the binding of K^+ at its extracellular sites would have to be on the steep part of the binding curve. This means that the enzyme should have a lower K^+ affinity than is usually observed in studies of purified enzyme. Second, the concentration of Na^+ inside the cell would have to be high enough to not be rate-limiting. For astrocyte Na,K-ATPase to be responsible for K^+ uptake then, it might be quite different from the enzyme in other tissues: higher Na^+ affinity, and/or lower K^+ affinity.

Intracellular Na^+ activity in resting mammalian astrocytes has been estimated to be 20 to 25 mM (Ballanyi et al., 1987), which is higher than in most cell types (see Chapter 18, this volume). Theoretically Na^+ may also enter locally through Na^+ channels, Na^+:transmitter uptake systems, or Na^+:K^+:Cl^- cotransport, supplying the Na,K-ATPase with enough Na^+ to support the exchange for extracellular K^+. Na^+ may also be supplied to some extent by cell coupling. Injection of current carried by Na^+ into mouse oligodendrocytes causes a passive exit of K^+, as measured with intracellular K^+ electrodes, and after the current pulse, K^+ levels were observed to be restored

via the ouabain-sensitive Na,K-ATPase (Kettenmann et al., 1987). Interestingly, recovery was similar if Li^+ or tetramethylammonium ion was ionophoresed into the cells instead of Na^+, which led to the suggestion that it was either the decrease in intracellular K^+ or the decrease in membrane potential, rather than the increase of intracellular Na^+, that activated the pump. With tetramethyammonium ion injection, however, recovery could be blocked by removing Na^+ from the extracellular fluid, implying that Na^+ had to enter to activate the Na,K-ATPase.

Evidence that astrocyte Na,K-ATPase has an unusually low affinity for K^+ has been reported (Franck et al., 1983; Guillaume et al., 1990; Reichenbach et al., 1992), although evidence for normal, high K^+ affinity has been published by other investigators (Kimelberg et al., 1978; Averet et al., 1987; reviewed in Stahl, 1986; Sweadner, 1989)]. Unpublished results from this laboratory, obtained with partially-purified Na,K-ATPase from cultured astrocytes, shows K^+ affinity as high as that of enzyme from axolemma. More physiological techniques, such as whole-cell patch-clamp, need to be applied to resolve the discrepancies. There are reports of cardiac glycoside-sensitive ATPase activity that is independent of Na^+ and/or K^+ in cultured astrocytes (Sweadner, 1983) and in retinal Müller cells (Reichenbach et al., 1987). Whether this is a related, but undiscovered, ATPase or a modification of the Na,K-ATPase remains to be determined, as well as its role in glial physiology.

A consequence of a large activation of the Na,K-ATPase by extracellular K^+ would be to hyperpolarize, not depolarize the cell, because the enzyme is electrogenic. *In vivo,* elevation of extracellular K^+ depolarizes glia, but a hyperpolarizing effect, which may be due to Na,K-ATPase, was uncovered when Ba^{2+} was used to block K^+ channels (Ballanyi et al., 1987).

The possibility that K^+ clearance is mediated by rectifying K^+ channels and/or a Na^+:K^+:Cl^- cotransport carrier is still quite strong. The Na,K-ATPase in glia would always be needed to extrude the Na^+ that comes in via other proteins such as Na^+-dependent neurotransmitter uptake systems and Na^+ channels (see Chapter 15). The open question is whether the Na,K-ATPase in astrocytes is specialized for a role in K^+ clearance, and quantitatively how important this is relative to the other mechanisms. As detailed below, astrocytes express the same isoforms of Na,K-ATPase α subunit and perhaps β subunit that are found in kidney, skeletal muscle, and many neurons.

ISOFORMS OF THE Na,K-ATPase

The Na,K-ATPase has two kinds of subunits, a 112,000 Dalton subunit called α, and a smaller glycoprotein subunit (32,000 Dalton of protein) called β (Figure 16-4). The α subunit has the binding sites for ATP and cardiac glycosides, and shows regions of sequence homology with a large family of ion-transporting ATPases, even those in protists (Lingrel et al., 1990). The β subunit is known to play a role in the biosynthesis and targeting of the enzyme to the plasma membrane, but its role in enzyme activity is not well understood. The two subunits have never been separated without irreversible loss of activity, however, and α synthesized in the absence of β is not active. Dimers of α and β are active, but there is experimental evidence to suggest that dimers may also associate to form functional tetramers.

There are three well-characterized isoforms of the α subunit, known as α1, α2, and α3 (Sweadner, 1989). Each is the product of a different gene, on different chromosomes (Lingrel et al., 1990). The genes show about 85% identity between isoforms, but each isoform shows 90 to 99% identity between vertebrate species (Takeyasu et al., 1990). All of the isoforms catalyze Na^+ and K^+-dependent ATPase activity, and all are inhibited by cardiac glycosides. The β subunit is also found in several isoforms derived from separate genes: two have been described in mammals and birds (β1 and β2) and a third in amphibians (β3). The sequences of the β subunit isoforms are more divergent than for the α isoforms: typically only 35 to 40% identity. There are also other closely related ATPases, such as H,K-ATPases, which have homologous α and β subunits, but these have not yet been described in glia.

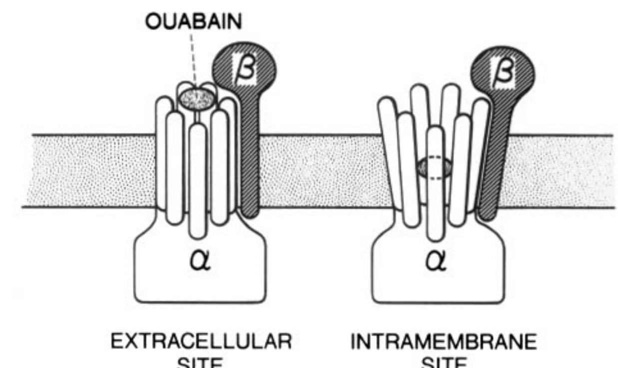

FIG. 16-4. Subunit composition of the Na,K-ATPase. The Na,K-ATPase α subunit spans the membrane multiple times, and has the binding sites for ATP and ouabain. The β subunit spans the membrane only once, and exposes most of its mass to the extracellular surface. Homologous ATPases like Ca^{2+}-ATPase do not have β subunits, but Na,K-ATPase will not fold correctly without one. The figure contrasts two possible locations for the location of the ouabain binding site: extracellular and between transmembrane segments. [From Sweadner (1993), with permission.]

There is abundant evidence, obtained with both isoform-specific antibodies and isoform-specific mRNA probes, that the expression of the Na,K-ATPase isoforms is tissue-specific and cell type-specific (Sweadner, 1989; Lingrel et al., 1990). Not surprisingly, the brain expresses all of the isoforms. More than one isoform is frequently expressed in the same cell simultaneously. If any α type can associate with any β type, then six different combinations are possible for mammals. It is quite likely that additional β subunits will be discovered.

CARDIAC GLYCOSIDE AFFINITY DIFFERENCES: A USEFUL TOOL

The α isoforms can differ in their ouabain affinity, depending on the animal species (Sweadner, 1989; Lingrel et al., 1990). In the rat, affinities for α1 are approximately 3×10^{-5}M; for α2, 10^{-7}M; and for α3, 3×10^{-8}M. Measurement of the binding of [^{3}H]ouabain to the lowest affinity form, α1, is for all practical purposes impossible because of its rapid dissociation during washes, and so detection of specific [^{3}H]ouabain binding in preparations derived from the rat indicates the presence of α2 or α3.

The molecular basis of the difference in ouabain affinity is now well understood (Lingrel et al., 1990; Sweadner, 1993). Substitution of one or a few critical amino acids in an extracellular segment of the α subunit, or the nearby transmembrane segments, is all that is needed to convert α1 with a low affinity (from a species like rat) to α1 with a high affinity (like those from species like sheep or human). Substitution of the β subunit is without effect.

The apparent ouabain affinities actually vary depending on the experimental conditions, since ouabain binding is highly dependent on the conformational state of the enzyme. Ouabain binding affinity is reduced by elevated extracellular K^+, for example, and binding will not occur to a significant extent in conditions where the enzyme cannot become phosphorylated at the active site (i.e., in the absence of ATP or P_i).

In preparations containing more than one isoform, low concentrations of ouabain (10^{-6} to 10^{-5} M) can be used to selectively inhibit α2 or α3. The relative contributions of α2/α3 and α1 are then estimated by subtraction. With intact cells, however, this experimental approach can be problematical, since inhibition of the high-affinity ATPase activity perturbs the intracellular Na^+ concentration and complicates the interpretation (McGill, 1991; McGill and Guidotti, 1991).

Na,K-ATPase ISOFORM EXPRESSION IN GLIA

The existence of Na,K-ATPase isoforms might explain some of the puzzling controversies in the literature if they have different functional properties. All of the five known Na,K-ATPase subunit types are found in the nervous system, and four out of five have been detected in glia: α1, α2, β1, and β2. Na,K-ATPase isoform expression in the nervous system has been reviewed (Sweadner, 1989, 1991, 1992; B. Schneider, 1992).

α Isoforms in Glial Cell Cultures

As shown below, astrocytes *in situ* can be demonstrated to express both α1 and α2 isoforms of the Na,K-ATPase. Glial cultures can be prepared that express only α1, or both α1 and α2. Early studies were done with cortical glial cultures from newborn rodents. Two criteria were used for detecting isoforms: the presence of low-affinity (α1) and high affinity (α2 and/or α3) ouabain sites, and the presence of two closely spaced bands of α subunit on SDS gels.* Marks and Seeds (1978) observed that in reaggregating mouse brain cell cultures, where both neurons and glia survived, both low and high-affinity sites were present when measured by the inhibition of Na,K-ATPase activity and by the inhibition of K^+ uptake. Conversely, in monolayer cultures, where neurons did not survive, only the low-affinity site was detected by ATPase assay or high affinity [^{3}H]ouabain binding. Sweadner (1979) found only low-affinity ouabain sites in rat cortical glial cultures as measured by inhibition of ATPase activity, and in addition, only the α1 electrophoretic band was detected on SDS gels. Membranes from whole brain had two ouabain affinities and two electrophoretic bands. Inoue et al. (1988), like Marks and Seeds (1978) detected only low-affinity ouabain sites in rat astrocyte cultures, both by inhibition of ATPase activity in membranes and of K^+ influx in cells, while neuronal cultures had both sites. Markwell et al. (1991) confirmed the virtual absence of high-affinity

*It is commonly observed that α1 migrates faster than α2 and α3 on SDS gels (Sweadner, 1979), although its true molecular weight is actually slightly higher. This property has sometimes been used successfully as a tool for isoform detection. It is also true, however, that apparently homogeneous α subunit types can be induced to split into two bands in different experimental conditions (Sweadner, 1990). The anomalous migration is thought to be due to peculiarities of SDS binding to hydrophobic stretches in the protein. Gel doublets of α are not sufficient proof by themselves of the presence of two isoforms without other, independent evidence.

[^{3}H]ouabain sites for glial cultures derived from either cortex or hippocampus of the mouse. They found that glia alone had only 4 to 8% of the specific [^{3}H]ouabain binding found in cultures that were additionally seeded thinly with neurons. Treatment with NMDA to kill neurons resulted in loss of about half of the [^{3}H]ouabain binding after 5 days. All these studies suggested that only α1 is found in cultured glia.

Other investigators, however, reported finding both high- and low-affinity ouabain sites in cultured glia. Walz and Hertz (1982) observed ouabain inhibition of K^+ uptake into mouse cortical astrocyte cultures at both low and high concentrations. Astrocytes grown in the presence or absence of dibutyryl cAMP for 2 to 3 weeks (to promote morphological differentiation) had similar biphasic inhibition curves (Walz and Hertz, 1982). Atterwill et al. (1984) also found both high- and low-affinity sites in astrocyte cultures, as well as in freshly isolated enriched astrocyte preparations. Both groups' observations had one thing in common: the high-affinity component was detected when cells were either loaded with Na^+ prior to assay, or preincubated with ouabain for 30 minutes, which would also elevate intracellular Na^+. This would maximize the activity of the Na,K-ATPase and also increase the rate at which low concentrations of ouabain saturate the high-affinity sites. Thus these studies raise the possibility that cultured glia may express both α1 and α2, but that α2 is only detected in some assays. This does not explain why no α2 was seen on gels (Sweadner, 1979) or why no high-affinity site was seen in ATPase assays of membrane preparations when Na^+ was not rate-limiting (Marks and Seeds, 1978; Inoue et al., 1988).

Evidence that α2 can be expressed in astrocytes in culture came from mRNA analysis of brain cells grown in culture as reaggregates (Corthesy-Theulaz et al., 1990). The mRNA for all three α isoforms was found in reaggregates after 15 days in culture. The α2 isoform mRNA levels had not yet risen very much after only 7 days in culture, in contrast to α1 and α3 mRNA levels, indicating that accumulation of α2 mRNA was delayed. When reaggregates were treated with cytosine arabinoside at an early time (when the drug eliminates 90 to 97% of glial marker expression by killing proliferating glia) the delayed appearance of α2 mRNA was essentially abolished. In contrast, when neurons were killed by cholera toxin, α2 mRNA levels were markedly increased. The expression of α3 mRNA was unaffected by killing glia, and nearly abolished by killing neurons. Concepts have thus evolved since the early observation of Marks and Seeds (1978): the brain cell reaggregates are now understood to have high-affinity ouabain sites, not only because of the presence of α3 in neurons, but also because of α2 in glia.

Why then is only low-affinity Na,K-ATPase (α1) so often seen in astrocyte monolayers? Recent experiments in my laboratory have shown that, while α1 expression is always seen in cortical glial monolayer cultures, α2 expression is seen only when conditions are permissive for the differentiation or proliferation of process-bearing glial cells. The process-bearing glial cells are not themselves the exclusive locus of the α2, however. Some process-bearing cells express only α1, while flat cells in their vicinity express α2 (K. Sweadner, unpublished observations). The discrepancies in the literature are likely to be due to the plasticity of glia and the variability and heterogeneity of cortical glial cultures. There is abundant precedent that glia in culture are not terminally differentiated. Even the expression of voltage-dependent ion channels is modified by culture environment and cellular interactions (see Chapter 12, this volume); it should come as no surprise that the same is true for an ion pump.

α *Isoform Localization* In Situ

Much has been learned about the cellular distribution of Na,K-ATPase isoforms in the nervous system. There is some evidence that α3 is expressed in many neurons while α2 is expressed in glia, α1 being found in both. This idea originated with the observation of prominent staining for α3 in large-diameter pyramidal neurons, both by immunocytochemistry and *in situ* hybridization (J. Schneider et al., 1988; Brines et al., 1991; McGrail et al., 1991a), while a majority of immunoreactive α2 and α2 mRNA had a diffuse distribution suggestive of glia (Filuk et al., 1989; McGrail and Sweadner, 1989; Anderson et al., 1991; McGrail et al., 1991a). While this generalization has some merit, a closer look at individual cell types, particularly smaller cells and those with less abundant Na,K-ATPase, suggests that isoform expression is more cell type-specific than cell class-specific. It is clear that not all neurons express α3, and not all glia express α1. Neurons have been unambiguously shown to express α1, α2, or α3. The only cell class-specific generalization that has stood up so far is that α3 has never been detected in a glial cell. It is present abundantly, along with α1, in the retinal horizontal cell, however. This is a cell with such unusual characteristics (no synaptic vesicles; extensive intercellular coupling) that it has been considered to be glialike in some respects.

Any given neuronal cell type may express 1 or 2 isoforms simultaneously. For example, α1 and α3

have been detected in retinal ganglion cells, amacrine cells, and horizontal cells (McGrail and Sweadner, 1986, 1989), in hippocampal pyramidal cells (Brines et al., 1991; McGrail et al., 1991a; Pietrini et al., 1992), and in subpopulations of dorsal root ganglion cells (Mata et al., 1991; J. M. Phillips and K. J. Sweadner, unpublished observations). Many large-diameter projection neurons (cortical and cerebellar pyramidal cells for example) express α3 (J. Schneider et al., 1988; Brines et al., 1991; Hieber et al., 1991), while smaller diameter neurons (cerebellar granule cells, for example) express α1 (Brines et al., 1991; Hieber et al., 1991). This also does not stand up as a general rule, however, because of the selective expression of α1, for example, in the large somata of certain brainstem nuclei and cortical strata (Brines et al., 1991; Hieber et al., 1991; McGrail et al., 1991a; Watts et al., 1991), and of α3 in retinal horizontal and bipolar cells (McGrail and Sweadner, 1989). In the dorsal horn of the spinal cord, some large neurons express both α2 and α3 (McGrail et al., 1991a; see also Watts et al., 1991); in the ventral horn, some express both α1 and α3 (Mata et al., 1991). Besides spinal motoneurons, α2 has been found to be expressed in a retinal amacrine cell (McGrail and Sweadner, 1989). Whether α2 is expressed in hippocampal pyramidal cells has been controversial. In two studies of *in situ* hybridization α2 mRNA was seen (Filuk et al., 1989; Brines et al., 1991), while in another it was not (Watts et al., 1991). Immunocytochemical labeling showed strong α2 stain around the cells, but whether the stain included the plasma membrane of the pyramidal cells themselves, as opposed to surrounding glia, was not clear (McGrail et al., 1991a).

The most unambiguous evidence for the presence of α1 and α2 in glia has come from immunocytochemistry. Isolated retinal Müller cells all express α1, but a subpopulation expresses α2 as well (McGrail and Sweadner, 1989). Colocalization of α1 and α2 with GFAP stain (glial fibrillary acidic protein) has been seen in optic nerve (McGrail and Sweadner, 1989) (Figure 16-5). At high magnification, the distinction between the glial localization of α2 and the axonal localization of α3 in spinal cord lateral white matter is striking (McGrail et al., 1991b) (Figure 16-6).

In situ hybridization in glia is usually less distinct than in neuronal somata and more difficult to pinpoint with certainty. At low resolution, α2 and some α1 hybridization has been seen to be diffuse (Filuk et al., 1989; Watts et al., 1991) or localized at low levels in glial-enriched areas (Brines et al., 1991), while α3 and some α1 hybridization is easily seen to be in identifiable neuronal cell bodies. Figure 16-7 shows the clustering of α1, α3, and β1 mRNA in cerebellar Purkinje cell bodies, while α2 and β2 mRNA appear to be located diffusely in adjacent cells, presumably the Bergmann glia (Watts et al., 1991). In the same figure, sensory neurons of the dorsal root ganglion were labeled with α1 and α3 probes, while nonneuronal cells were labeled for α1. Hybridization for α2 was seen in sections of sensory nerve, where only nonneuronal cells have nuclei. Another example is shown in Figure 16-8, where clusters of hybridization for α1 and α3 can be identified in neuronal cell bodies in the superior cervical ganglion, while α2 hybridization is diffuse, as expected for the nonneuronal cells. Schwann cells in sciatic nerve have also been observed to hybridize with probe for α1 mRNA, and white matter tracts of the spinal cord were found to have signal for α1 in glial (presumed oligodendroglial) cell bodies, but not α3 (Mata et al., 1991). One additional striking nonneuronal location of α2 mRNA hybridization is the meninges or arachnoid membrane (Brines et al., 1991; Watts et al., 1991); high-resolution studies have not yet determined whether this labeling is in meningeal cells or closely-apposed astrocytes.

β *Isoforms*

While the Na,K-ATPase α subunit has the multiple-spanning structure expected of an ion transport protein, the β subunit is primarily an extracellular globular protein anchored to the membrane by a single transmembrane segment (Figure 16-4). The localization of the β isoforms has not been as extensively studied as that of the α isoforms, but there is some indication that β2, like α2, may be more commonly expressed in glia. In contrast to β1, β2 mRNA shows a remarkable regional concentration in cerebellar cortex compared to other brain regions (Pagliusi et al., 1990; Anderson et al., 1991). The distribution of β2 there (at low magnification) is similar to that of β1 (Anderson et al., 1991), but at higher magnification β2 mRNA hybridization shows a distribution similar to that of α2 in Bergmann glia, near but not in the neurons (Pagliusi et al., 1990; Watts et al., 1991) (Figure 16-7). Different studies also examined β1 mRNA (Filuk et al., 1989), β2 mRNA (Pagliusi et al., 1990), or both (Watts et al., 1991) in the hippocampal formation. Signal for β1 was highly concentrated in the regions of highest neuronal density, while β2 signal was more distributed, and at high magnification was seen to be associated with glia. A highly specialized neuronal cell, the photoreceptor, expresses β2 but not β1, however, providing evidence that β2 is not an exclusive marker of glia (B. Schneider et al., 1991).

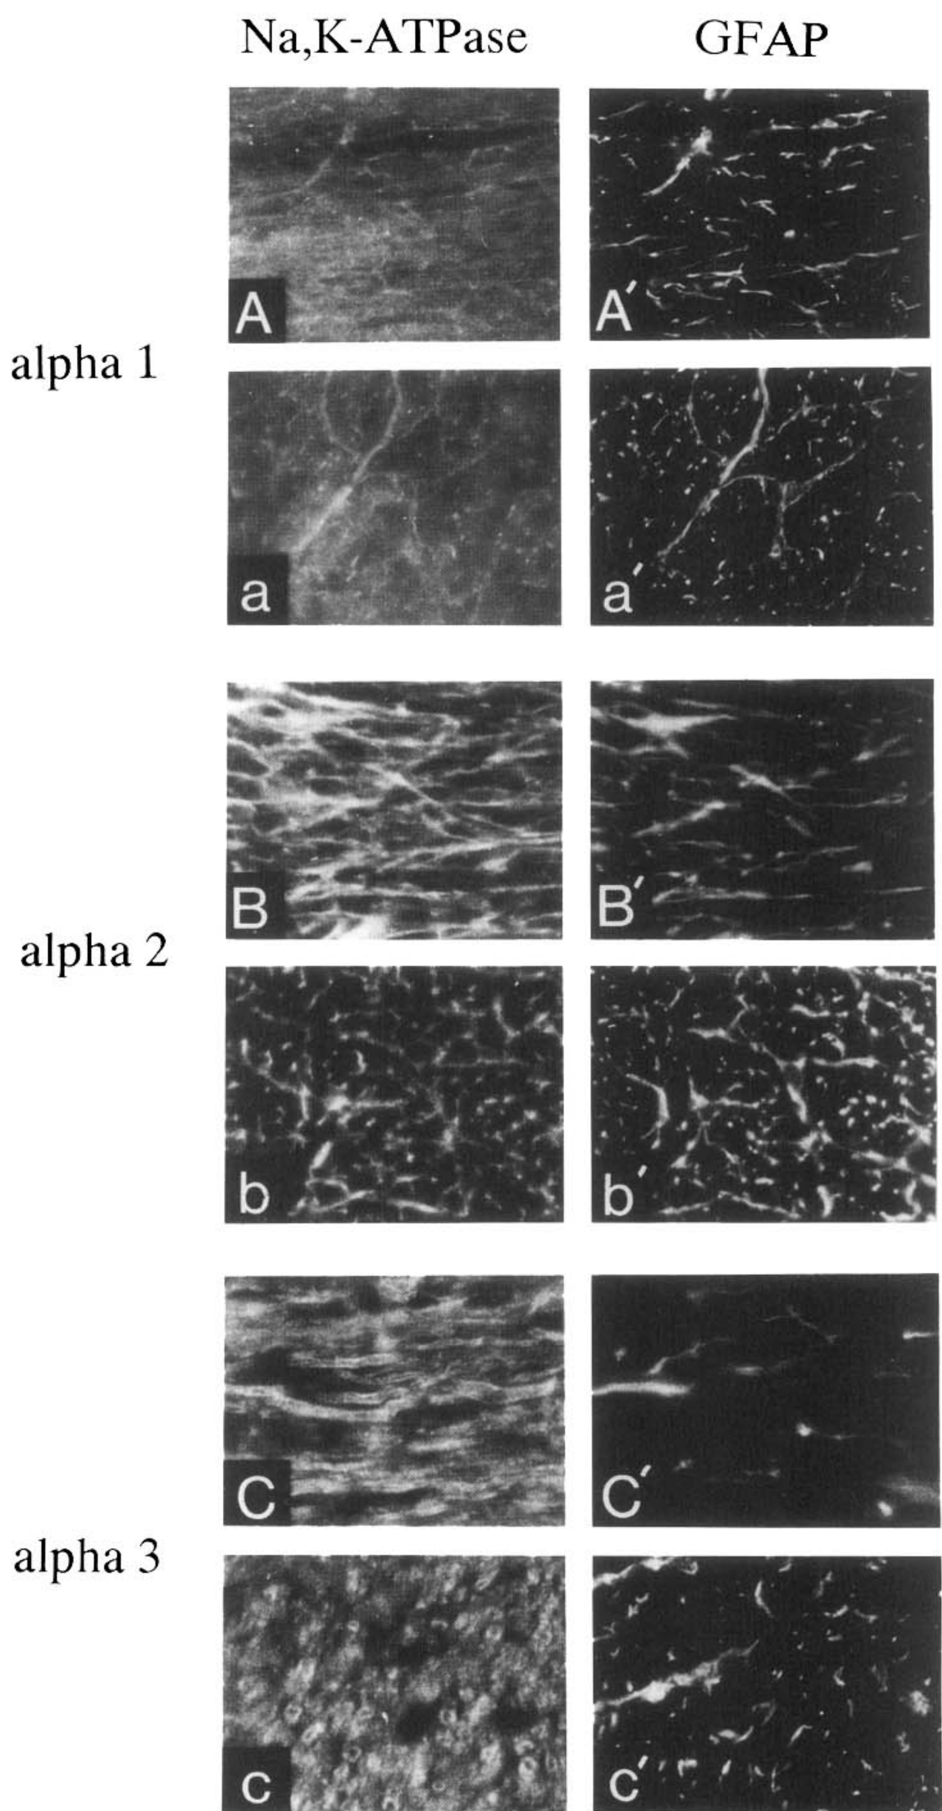

FIG. 16-5. Na,K-ATPase α isoforms in optic nerve. Immunofluorescence was used to stain Na,K-ATPase isoforms. Rat optic nerve was cut in both longitudinal section (*A*, *B*, *C*) and cross section (*a*, *b*, *c*), and double-labeled with monoclonal antibodies (*left*) against $\alpha 1$ (*A*), $\alpha 2$ (*B*), and $\alpha 3$ (*C*) and a rabbit antiserum against a glial marker protein, GFAP (*right*). Both $\alpha 1$ and $\alpha 2$ staining coincided with the glial marker. In contrast, $\alpha 3$ staining outlined the axons. It is notable that the Na,K-ATPase in axons is not confined to nodes of Ranvier. [From McGrail and Sweadner (1989), with permission.]

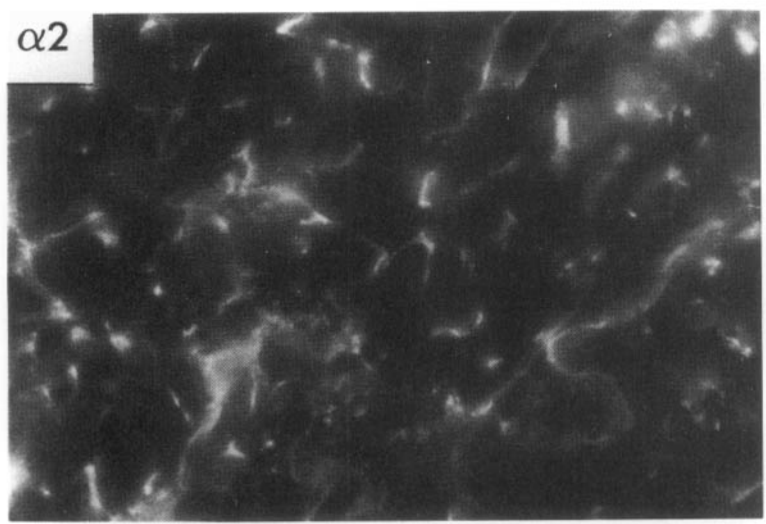

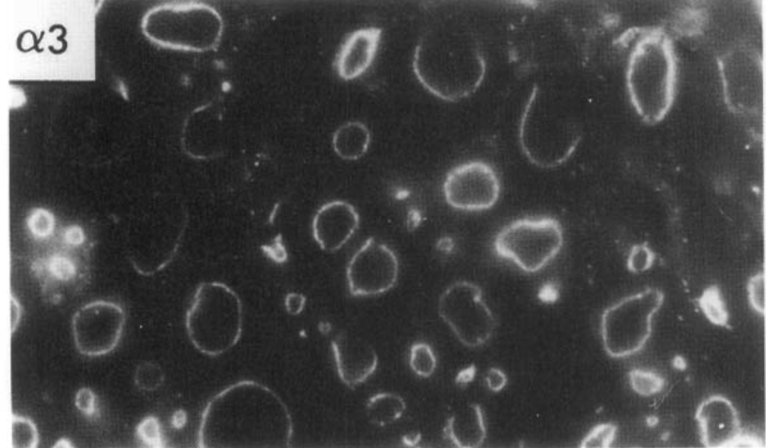

FIG. 16-6. α2 and α3 localization in spinal white matter. Cross sections of white matter adjacent to the dorsal horn were stained with monoclonal antibodies against α2 and α3 by immunofluorescence. The α2 antibody stained glia between the axons, while the α3 antibody ring stained both large- and small-diameter axons. Myelin was unstained, and showed as dark rings surrounding the axons. [From McGrail et al. (1991b), with permission.]

Considerably less immunocytochemistry has been done for the β isoforms because of the lack of a suitable set of antibodies. Staining for β2 has been seen in some (but not all) cultured cortical astrocytes from the mouse, as well as in small cerebellar neurons (Gloor et al., 1990). Recently, however, an antibody originally described to be against a neuron-specific glycoprotein (Beesley et al., 1987) has been found to react with β2 (Gloor et al., 1992; K. Sweadner, unpublished observations).

The cDNA for the β2 subunit was first isolated not as a component of the Na,K-ATPase, but as an adhesion molecule found on cerebellar glia (adhesion molecule on glia [AMOG]) (Pagliusi et al., 1989). Its role in neuron-glia adhesion was documented by the blocking actions of a monoclonal antibody (Antonicek et al., 1987). AMOG (β2) was later shown to be a subunit of the Na,K-ATPase, and to preferentially associate with α2 in detergent extracts of mouse brain (Gloor et al., 1990). It was independently cloned from rat and human brain (Martin-Vasallo et al., 1989) and shown to copurify with Na,K-ATPase α (Shyjan et al., 1990b). The molecular mechanism of its role in adhesion is not yet understood in detail. Two observations make it likely that adhesion mediated by β2 is independent of any structural or functional role it has in the Na,K-ATPase. First, β2 subunit free of α subunit will adhere to neurons when reconstituted into liposomes (Antonicek and Schachner, 1988), and second, AMOG-mediated neuron-glia adhesion can occur even when the Na,K-ATPase is inhibited by ouabain (Gloor et al., 1990). The glycosylated β2 may be the recognition target of a more conventional adhesion protein; it shares the L3 carbohydrate epitope with other adhesion proteins L1 and MAG (Gloor et al., 1990).

FUNCTIONAL DIFFERENCES BETWEEN Na,K-ATPase ISOFORMS

A question of considerable importance is how the isoforms differ functionally, and whether these dif-

ferences play a role in glial physiology. A few things are known about their substrate affinities and possible selective regulation by hormones, although there is much more controversy than consensus.

Possible differences in affinity for Na^+ have received the most attention, although a clear picture has not yet emerged. Affinity for Na^+ for axolemma Na,K-ATPase preparations containing α2 and α3 has been reported to be higher than in kidney preparations containing α1 (Sweadner, 1985). Several enzymological criteria suggest that this may be related to the tendency of α1 to adopt the E2 conformation more than α2 + α3 (reviewed in Sweadner, 1989). When the Na^+ affinity of pinealocyte membrane Na,K-ATPase, containing α3, was compared to that of kidney Na,K-ATPase (α1), it was found that the α3 had a higher affinity (Shyjan et al., 1990a), although both measured affinities (11 mM and 20 mM, respectively) were substantially lower than reported for axolemma and kidney at the same concentration of K^+ (6 mM and 10 mM) (Sweadner, 1985). When α1, α2, and α3 were expressed separately in transfected HeLa cells, α1 and α2 were found to have similar affinities ($K_{0.5}$ about 5 mM) while α3 was of lower affinity ($K_{0.5}$ about 12 mM) (Jewell and Lingrel, 1991). That α1 and α2 have essentially the same Na^+ affinities was determined independently in transfected CV-1 cells with a dif-

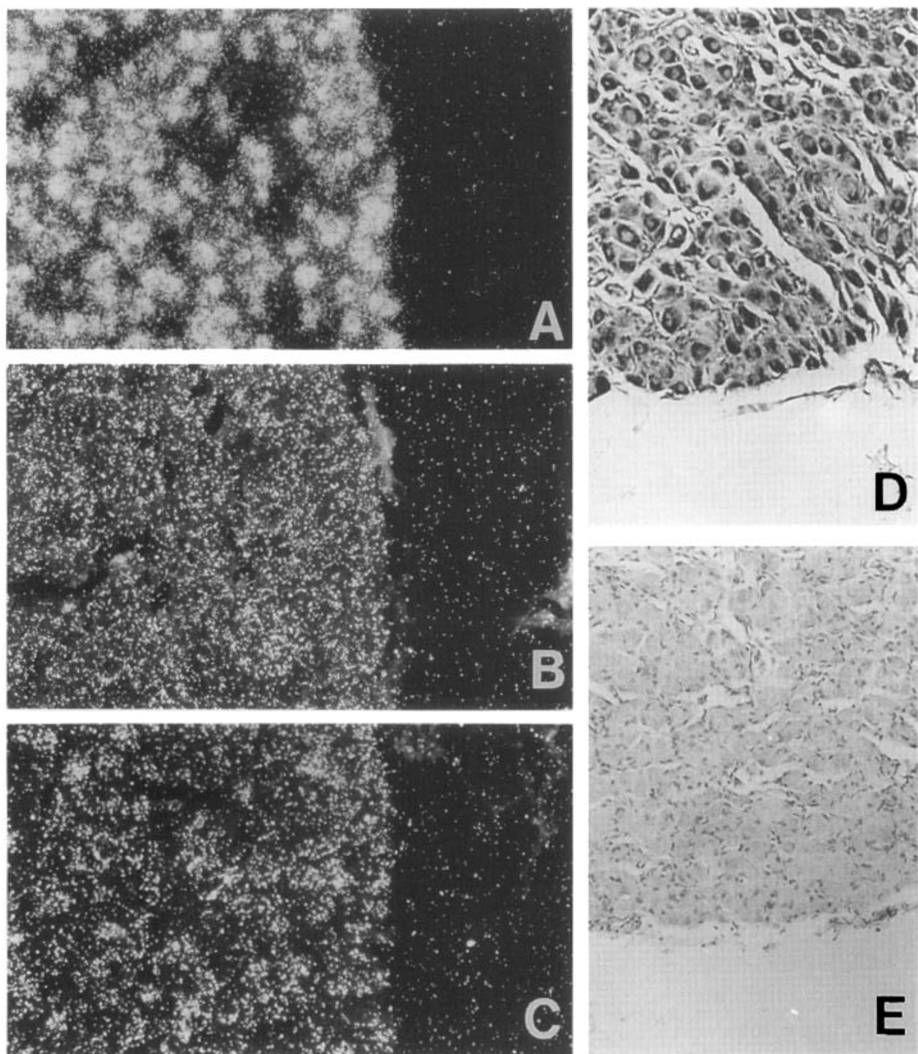

FIG. 16-8. Darkfield photographs of hybridization for $\alpha 1$ (*A*), $\alpha 2$ (*B*), or $\alpha 3$ (*C*) are shown; the signal is the white spots. Hybridization signal for $\alpha 1$ was heavily concentrated in neuronal cell bodies, and $\alpha 3$ was concentrated in a subset of them. Hybridization for $\alpha 2$, in contrast, was very diffuse. *In situ* hybridization for α isoforms in superior cervical ganglion. Sections of adult rat superior cervical ganglion (a ganglion of the sympathetic nervous system) were stained with hematoxylin/eosin (*D*) to highlight the neuronal cell bodies or with methylene blue (*E*) to highlight the non-neuronal cell nuclei. [T. Cova, K. Sweadner, and V. H. M. Herrera, unpublished observations.]

ferent assay: $^{86}Rb^+$ uptake in Na^+-loaded cells (Shyjan et al., 1991). The affinity of α3 in transfected HeLa cells (Jewell and Lingrel, 1991) was very similar to that of α3 in pineal cells (Shyjan et al., 1990a), but α3 Na^+ affinities were lower than measured in axolemma, and kidney α1 affinity measurements have not been very reproducible from laboratory to laboratory. Jewell and Lingrel (1993) made chimeras of α1 and α3 to attempt to pinpoint regions essential for the difference in Na^+ affinity in the sequence of the α subunit. The outcome was that no single region determined Na^+ affinity. Such disparate conclusions suggest that Na^+ affinity is not an unchangeable property of each Na,K-ATPase isoform, but rather that it is something modified by regulation or environment, or even by association with different β subunits.

Alteration of Na,K-ATPase Na^+ affinity by insulin has in fact been extensively investigated by Guidotti and collaborators. Adipocyte α2 was originally thought to be of low Na^+ affinity unless treated with insulin (Lytton, 1985), but when this was reinvestigated in adipocyte ghosts it was shown that α1 and α2 affinities were really very similar, and changes in intracellular Na^+ concentration had given a deceptively high value for the relative level of activity of the α1 isoform (McGill, 1991). Simulations of the effect of inhibiting one isoform while raising intracellular Na^+ allowed a calculation of the effect of insulin on both K_m and V_{max} (McGill and Guidotti, 1991): it was concluded that the K_m for both α1 and α2 could be affected by insulin, but that the major physiological effect was more likely on the V_{max} for α2. Similar phenomena were reported in synaptosomes, containing all three isoforms of the Na,K-ATPase (Brodsky, 1990; Brodsky and Guidotti, 1990). The mechanisms by which insulin exerts its effects are still unknown.

Potassium affinity is of particular interest because of its potential role in glial physiology, but again, no

consistent pattern has been seen when Na,K-ATPase isoforms have been compared. In transfected HeLa cells, α1 and α2 had indistinguishable affinities of 0.45 mM, while α3 had a higher affinity, 0.27 mM, measured in 30 mM NaCl (Jewell and Lingrel, 1991). When kidney (α1) and pinealocyte (α3) membranes were compared, α1 had an affinity of 1.75 mM, while α3 had an affinity of 2.1 mM, measured in 130 mM Na^+ (Shyjan et al., 1990a). In purified enzyme preparations from kidney (α1) and axolemma (α2 + α3), K^+ affinities were essentially indistinguishable (0.88 mM and 0.91 mM), measured in 140 mM Na^+ (Sweadner, 1985). Recently, however, evidence has been presented that the isoform of the β subunit affects the K^+ affinity of the Na,K-ATPase (Jaisser et al., 1992). While β1 is the only isoform present in the HeLa cells and kidney preparations, β2 predominates in pinealocytes, and both may be present in axolemma.

SUMMARY

The role of the Na,K-ATPase in glia is still surprisingly controversial. The discovery of molecular heterogeneity of its subunits has been a big step forward, but detailed cellular physiology and biophysical studies are needed to answer some of the major questions, such as whether and how much the pump contributes to K^+ redistribution, and why astrocytes express more than one isoform of both α and β subunits. The question of whether astrocyte Na,K-ATPase has a low affinity for K^+, making it suitable to play a role in K^+ clearance, remains controversial.

17 Modulation and control of intracellular calcium

STEVEN M. FINKBEINER

The importance of understanding glial calcium (Ca^{2+}) control seems clear: the calcium ion modulates or mediates many cellular functions and may underlie a form of long-range signaling (Finkbeiner, 1993). Transient cytosolic calcium changes produce several immediate, intermediate, and long-term changes in glial structure and function. Within seconds of a calcium increase, glial calcium-activated potassium channels open, transiently changing the composition of the interstitial space (Barres et al., 1990). Calcium increases may quickly mobilize arachidonic acid, which in turn may alter extracellular glutamate levels (Marin et al., 1991b; El-Etr et al., 1992). Calcium-activated protein kinases such as calcium/calmodulin-dependent kinase (Fukunaga et al., 1988; Schulman et al., 1992) and phospholipid-dependent protein kinase C (PKC) (Neary et al., 1986; Murphy et al., 1993) translate transient calcium changes into longer-lasting functional changes through phosphorylation of enzymes, ion channels, and the cytoskeleton (Huganir, 1987; Harrison and Mobley, 1992; Medrano et al., 1992). Calcium increases produce long-term changes by modulating proteolytic cytoskeletal remodeling (Schlaepfer and Zimmerman, 1981; Bianchi et al., 1993) and glial gene expression (Trejo and Brown, 1991; Bagaglio et al., 1993), ultimately affecting glial proliferation (Meador-Woodruff et al., 1984; Supattapone et al., 1989) and differentiation (Hart et al., 1989). This chapter focuses on the cell biology and physiology of glial calcium, including its intracellular distribution, control mechanisms, and the temporal and spatial patterns of stimulus-evoked calcium change. Chapter 12 and Section IV discuss glial voltage-gated calcium channels and neurotransmitter receptors.

CALCIUM DISTRIBUTION AND HOMEOSTASIS

Cells distribute calcium among three functional compartments: extracellular space, cytosol, and restricted intracellular sites known as calcium stores or compartments. Normally, glia maintain an asymmetric distribution of calcium. Free cytosolic calcium is low (100 nM), extracellular calcium is high (2 to 5 mM), and the calcium content of intracellular stores can be very high (1 to 100 mM). Stimulation may evoke transmembrane influx of extracellular calcium or release of internally stored calcium sufficient to raise cytoplasmic levels to 1 to 2 μM (Finkbeiner, 1993).

Glia restore and maintain baseline calcium distribution by pumping calcium from the cytosol into internal stores or across the plasma membrane. Two main types of calcium pump, sodium-calcium exchangers and calcium-adenosine triphosphatases (ATPases), shuttle calcium between compartments in other cell types (Muallem, 1989). No direct proof exists for glial sodium-calcium exchange but several results suggest it occurs. The sodium-calcium exchanger depends on a transmembrane sodium gradient to extrude intracellular calcium. Sodium-free solution itself raises glial cytoplasmic calcium (Cornell-Bell and Finkbeiner, 1991; Delumeau et al., 1991; MacVicar et al., 1991) and alters the magnitude and shape of glial calcium responses (Cornell-Bell et al., 1990; Finkbeiner, 1991) (Figure 17-1). Calcium/ATPase localizes to glial plasma membranes (Mata et al., 1988) and endoplasmic reticulum (Maggio et al., 1991) and is active in central and peripheral nervous system glia (Mata and Fink, 1989). A calcium-hydrogen exchanger may pump calcium into internal stores of certain invertebrate glial cells (Keicher et al., 1991).

INTRACELLULAR CALCIUM STORES

According to one radiotracer study, the calcium content of glial intracellular stores exceeds free cytosolic calcium by a ratio of 20,000:1 (Walz and Wilson, 1986). The calcium is distributed among several intracellular structures, including cytoplasmic calcium-binding proteins, mitochondria, lysozomes, the Golgi apparatus, and elements of the endoplasmic reticulum; the endoplasmic reticulum-like store contains more calcium than the other organelles (Gambetti et

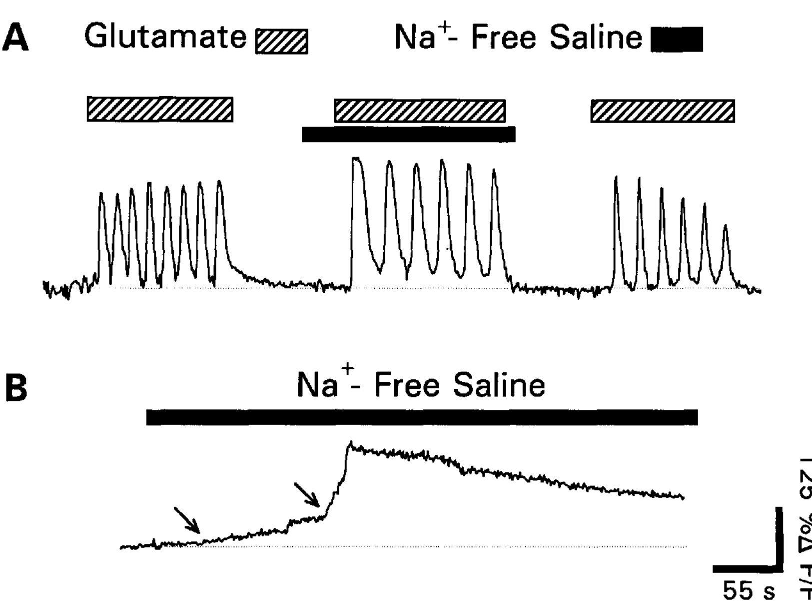

FIG. 17-1. Na^+-free saline application evokes glial Ca^{2+} increases and enhances stimulus-evoked Ca^{2+} responses. The figure shows fluo-3 fluorescence time-course traces from rat hippocampal type-1 astrocytes (Cornell-Bell et al., 1990; Finkbeiner, 1991). Na^+-free saline was prepared by isosmotic Na^+ substitution with impermeable *N*-methyl-D-glucamine or choline. The addition bars indicate the duration of glutamate or Na^+-free saline application. (A) Na^+-free saline increases the amplitude and duration of glutamate-evoked cytosolic Ca^{2+} oscillations. (B) The change to Na^+-free superfusate also marks the beginning of a slow steady rise in cytoplasmic Ca^{2+} (*first arrow*). Three minutes after Na^+-free saline washes on, the astrocyte spontaneously initiates a propagating Ca^{2+} wave, indicated by the abrupt Ca^{2+} rise (*second arrow*). Typically, ligand-induced Ca^{2+} increases have a spike and plateau shape (*see text*). However, Ca^{2+} increases in Na^+-free saline remain near peak levels for long periods and return toward baseline slowly.

al., 1975; Vidulescu et al., 1991). The location of calcium stores differs among glia types. In spinal cord ependymal cells, the calcium-containing endoplasmic reticulum elements have a vesicular-cisternal morphology and associate with cytoskeletal elements in cell processes (Gambetti et al., 1975). In central nervous system astrocytes, the analogous structures have a circular shape and appear throughout the cytoplasm. In hippocampal astrocytes, the perinuclear endoplasmic reticulum elements are particularly rich in calcium (Cornell-Bell and Finkbeiner, 1991). Calreticulin, a low-affinity, high-capacity calcium-binding protein, is probably present in glial endoplasmic reticulum and enables the organelle to store large amounts of calcium (Lytton and Nigam, 1992; Opas and Michalak, 1992). Certain invertebrate glia have calcium containing (50 to 100 mM) acidic organelles known as gliagrana that localize to glial processes extending into the perineuronal space (Keicher et al., 1991).

Certain glial calcium-containing organelles likely participate in intracellular signaling by undergoing stimulus-evoked calcium release. In other cell types, endoplasmic reticulum components mediate this function (Terasaki and Sardet, 1991). Glutamate, a neurotransmitter that releases internally stored calcium in astrocytes, shifts histochemical calcium staining to the cytoplasm from endoplasmic reticulum-like structures, mitochondria, and the nucleus (Cornell-Bell and Finkbeiner, 1991). Although mitochondria represent a large and dynamic internal calcium store, it is unlikely that they directly undergo ligand-induced calcium release (Zareba-Kowalska and Gajkowska, 1990; Gill et al., 1992).

The functional organization and biochemical control of intracellular calcium stores is a subject of intense study (for review see Berridge, 1993). There are at least two mechanisms by which internal stores release calcium. In one mechanism, a ligand binds to a surface receptor that activates phospholipase C (PLC) through a G protein or through a tyrosine kinase. Phospholipase C metabolizes phosphatidylinositol 4,5-bisphosphate to form inositol 1,4,5-trisphosphate (IP_3), which diffuses from the plasma membrane through the cytosol to activate a calcium channel located on intracellular stores (Terasaki and Sardet, 1991; Taylor and Marshall, 1992). Several lines of evidence suggest that this pathway is present in glia.

1. Most ligands capable of intracellular Ca^{2+} release also stimulate glial IP_3 production (Murphy and Pearce, 1987; Pearce et al., 1988).
2. Blocking intracellular Ca^{2+} release with 8-(*N,N*-diethylamino)octyl-3,4,5-trimethoxybenzoate (TMB-8), dramatically decreases Ca^{2+} responses to some IP_3-mobilizing ligands (Lin et al., 1992).
3. Some ligands that stimulate inositol turnover release Ca^{2+} from the same intracellular Ca^{2+} stores (McDonough et al., 1988; Lin et al., 1992).
4. Pertussis toxin (PTX), a protein that inactivates a subset of G proteins, diminishes glial Ca^{2+} responses to a few of the inositol-mobilizing ligands (Delumeau et al., 1991; Marin et al., 1991b).

5. Nanomolar concentrations of IP_3 produced by flash photolysis evoke rapid cytoplasmic Ca^{2+} increases in cerebellar astrocytes (Khodakhah and Ogden, 1993).
6. Inhibition of Ca^{2+}/ATPase, the enzyme that pumps Ca^{2+} into most internal stores, eliminates glutamate Ca^{2+} responses in astrocytes (Charles et al., 1993).

A second mechanism to release internal calcium is through calcium-induced calcium release (CICR) (Putney, 1986). Skeletal and cardiac muscle cells utilize CICR as the major mechanism to achieve excitation-induced cytoplasmic calcium increases. The calcium ion binds an IP_3 receptor homologue called the *ryanodine receptor*, which gates a sarcoplasmic reticulum calcium channel (for review see Taylor and Marshall, 1992). Glia express plasma membrane calcium-activated calcium channels; however, it is unclear whether such a channel regulates release of internal calcium stores (Puro, 1991b). In fact, ryanodine failed to elicit calcium responses itself or modulate glial calcium responses to glutamate or mechanical stimulation (Finkbeiner, 1991; Charles et al., 1993). Caffeine, which triggers CICR in other cell types, was similarly ineffective on cortical astrocytes (Charles et al., 1993).

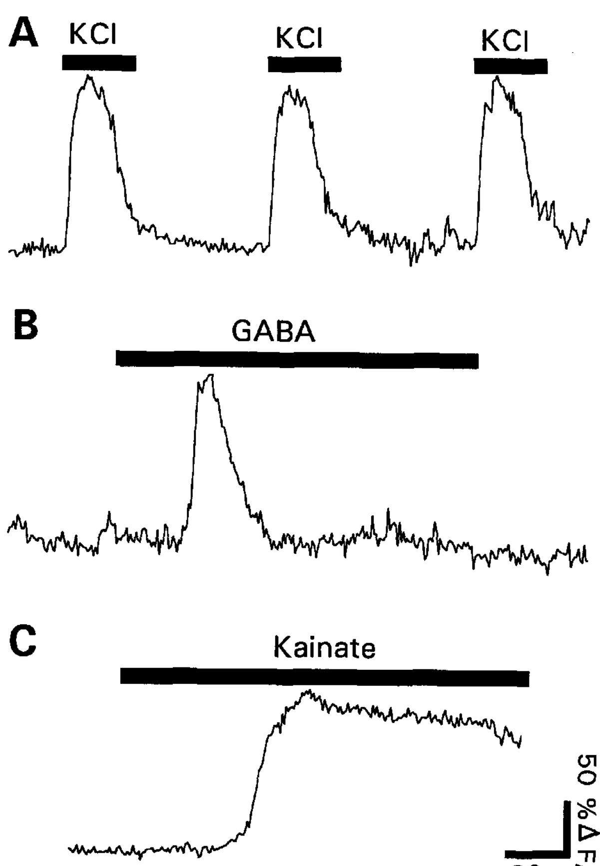

FIG. 17-2. Monophasic Ca^{2+} responses illustrated with fluorescence time-course traces from fluo-3 experiments on rat hippocampal type-1 astrocytes (Finkbeiner, 1991). (A) Ca^{2+} rises and falls quickly in response to depolarizing K^+ (55 mM) pulses (addition bars). Dihydropyridine (DHP)-sensitive voltage-gated Ca^{2+} channels likely mediate the rise as the removal of extracellular Ca^{2+} or the addition of the DHP, nimodipine blocks the K^+-induced Ca^{2+} rise (Finkbeiner, 1991). (B) GABA (100 μM) Ca^{2+} responses appear long after GABA washes on and disappear well before GABA washes off. (C) Kainate (100 μM) stimulates a cytoplasmic Ca^{2+} response, which gradually rises to a maximum then gradually declines to baseline, despite the continued presence of kainate.

PLASMA MEMBRANE CALCIUM CHANNELS

Voltage-Gated Calcium Channels

Glial cells possess several calcium-permeable plasma membrane ion channels. Sontheimer and Ritchie review glial voltage-gated calcium channels in Chapter 12, but a few points are particularly relevant to this discussion. Glia express several channels that differ in the membrane potential at which they activate, the amount of calcium conducted per single channel opening, and the rate and control of channel inactivation (Sontheimer, 1992). Channel activation triggers sufficient calcium influx to significantly raise glial cytoplasmic calcium levels (Jensen and Chiu, 1990, 1991; Finkbeiner, 1991; Fatatis and Russell, 1992; Munsch and Deitmer, 1992) (Figure 17-2). Finally, glial calcium channel expression depends on environmental factors and may be under neuronal control *in vivo* (Corvalan et al., 1990; MacVicar et al., 1991; Matute and Miledi, 1993).

Ligand-Gated Calcium Channels

Another heterogeneous group of glial plasma membrane calcium channels are not voltage-activated. Rather these channels open in response to certain ligands, cytoplasmic calcium increases, or deformation of the plasma membrane. For example, the glutamate analogues kainate or α-amino-3-hydroxy-5-methylisoxazole-4-proprionic acid (AMPA) activate receptor-gated calcium channels in Bergmann glia. Simultaneous electrophysiologic and fluorometric measurements show that activation of AMPA/kainate-sensitive glutamate receptors produces significant calcium influx independent of voltage changes (Müller et al., 1992). Quantitatively, calcium permeates the channel 1.5 times the rate of the monovalent ion, cesium. Bergmann glia express a particular subset of glutamate receptor subunits, which confer calcium permeability to the channels they comprise (Burnashev et al., 1992).

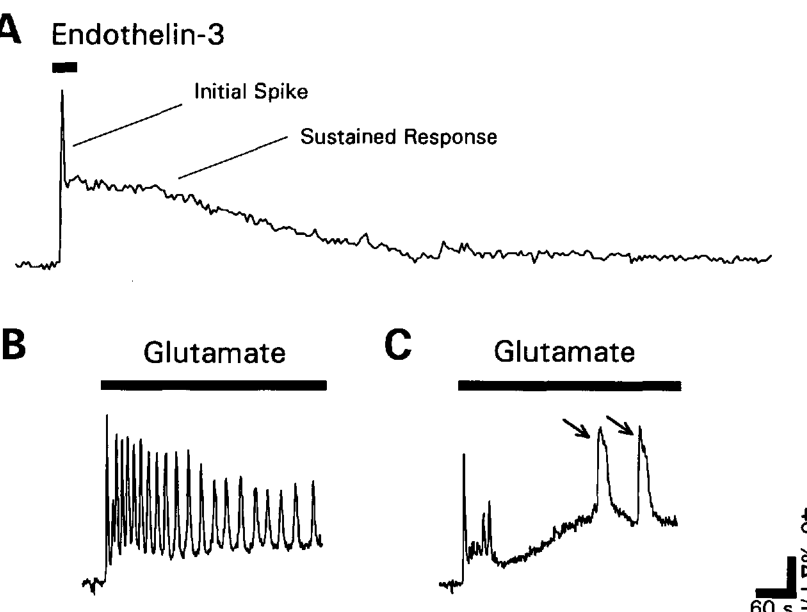

FIG. 17-3. Biphasic/polyphasic Ca^{2+} responses from fluo-3 experiments on rat hippocampal type-1 astrocytes (Finkbeiner, 1991). (A) The small peptide, endothelin-3, stimulates an initial Ca^{2+} spike lasting seconds and a sustained plateau lasting 20 to 30 minutes. The two components are labeled. The sustained component of glutamate Ca^{2+} responses (B) may manifest complex cytosolic Ca^{2+} oscillations or (C) may be interrupted by episodic broad-peaked Ca^{+} rises (*arrows*), which represent intracellular and intercellular Ca^{2+} waves.

Most studies find that another glutamate receptor subtype, the *N*-methyl-D-aspartate (NMDA) receptor, does not mediate glial calcium responses (Enkvist et al., 1989b; Glaum et al., 1990; Jensen and Chiu, 1990). However, two studies differ. In the study by Ahmed et al. (1990), a small minority of spinal cord astrocytes show NMDA-induced calcium increases in the presence of extracellular calcium. In the study by Holopainen and Åkerman (1990), NMDA induced a calcium 45 efflux from cultured cerebral astrocytes, which changed predictably upon application or withdrawal of NMDA antagonists. Recently, one group found high doses of NMDA elicited small non-magnesium-sensitive, non-glycine-sensitive inward currents in Bergmann glia (Müller et al., 1993). However, the NMDA responses did not produce detectable calcium rises. Perhaps the calcium responses detected in the earlier studies resulted from activation of voltage-gated calcium fluxes by NMDA-induced depolarization.

Some researchers suggest benzodiazepine and kappa-opiod receptors directly activate voltage-gated calcium channels. In support, benzodiazepines competitively inhibit the binding of nitrendipine, a dihydropyridine (DHP)-sensitive calcium channel blocker (Bender and Hertz, 1985). However, direct electrophysiological evidence is lacking, and follow-up data have raised doubts about the hypothesis (Pruss et al., 1991). Kappa-opiod receptor agonists trigger dihydropyridine-sensitive voltage-gated calcium fluxes, although the transduction mechanism is unclear (Eriksson et al., 1993).

Retinal Müller glia express two interesting calcium channels: one opens in response to cytosolic calcium increases, the other in response to plasma membrane deformation. The calcium-activated calcium channel is detectable in 50% of cells and has an average single-channel conductance of approximately 17 pS (Puro, 1991b). Cytosolic calcium concentrations govern the fraction of time in which the channel remains in the open state: single-channel openings increase 10-fold when calcium applied to the cytoplasmic side of excised patches increases from 10 nM to 10 μM. The second channel type, a "stretch-activated" ion channel, is permeable to both monovalent and divalent cations and has a single-channel conductance of 32 pS (Puro, 1991a). Channel activation produces sufficient calcium influx to increase calcium-activated potassium currents.

STIMULUS-EVOKED GLIAL CALCIUM SIGNALING

Glia show remarkably diverse and complex calcium responses to a variety of stimuli, including neurotransmitters, neuropeptides, neuromodulators, second messengers, depolarization, and mechanical stimulation (Finkbeiner, 1993) (Figures 17-2 and 17-3; Table 17-1). The shape of the calcium fluctuation ranges from a simple step-response to a complex oscillation: the latency and duration of responses vary too. Calcium responses may be restricted to single glial cells or propagate between cells. The complexity and diversity of glial calcium responses raise several intriguing questions. What glial signal transduction pathways must exist to produce such diversity? How do glial cells achieve sig-

naling specificity when different stimuli produce similar responses or a single stimulus produces diverse responses? Do these responses, particularly long-range glial signaling, occur *in vivo* and what purpose do they serve?

Response Classification

Glial calcium responses can be broadly classified as either monophasic or biphasic/polyphasic (Finkbeiner, 1993). Stimuli such as kainate, the inhibitory neurotransmitter gamma-aminobutyric acid (GABA), or depolarizing concentrations of potassium typically evoke simple monophasic responses (Figure 17-2). In monophasic responses, cytoplasmic calcium steadily climbs to a peak, then it may or may not decline to baseline: the rate of rise, plateau duration, and rate of return to baseline vary. By contrast, stimuli such as glutamate or the neuropeptide endothelin (ET) produce complex biphasic or polyphasic responses (Figure 17-3). In biphasic/polyphasic responses, calcium rises rapidly to form an initial spike, then falls to an intermediate level for an indefinite interval. The sustained calcium rise following the initial spike may manifest different patterns, including periodic calcium oscillations, large random calcium peaks, or a flat, featureless calcium plateau.

Calcium Source for Cytosolic Transients

The importance of the response categories partly relates to the mechanism and source of the calcium increase. Monophasic responses usually result from transmembrane calcium influx through ligand- or voltage-gated plasma membrane calcium channels: biphasic/polyphasic responses depend on second messenger-induced internal calcium release and variable amounts of calcium influx through plasma membrane calcium channels (Table 17-1). To test whether a stimulus-evoked response depends on influx of extracellular calcium, release of internal calcium stores, or both, one compares the response in the presence and absence of extracellular calcium. Extracellular calcium removal nearly eliminates calcium responses to some stimuli, such as depolarizing potassium (Finkbeiner, 1991; Munsch and Deitmer, 1992; van den Pol et al., 1992), but has no effect on responses to other stimuli, such as the inositol-mobilizing glutamate analogue, *trans*-1-aminocyclopentane-1,3-dicarboxylic acid (ACPD) (Cornell-Bell and Finkbeiner, 1991). The results are consistent with the idea that depolarization causes calcium influx through voltage-gated calcium channels, and ACPD releases internal calcium through IP_3.

Biphasic/polyphasic calcium responses depend on internal calcium release as well as extracellular calcium influx. The initial calcium spike primarily results from intracellular store release. In support, the spike usually persists in the absence of extracellular calcium. The nucleotide adenosine triphosphate (ATP), the glutamate analogues quisqualate and ACPD, the neurotransmitters histamine, acetylcholine (ACh), and norepinephrine, or the neuropeptides bradykinin and neuropeptide Y (NPY) each produce a calcium spike in calcium-free saline (Brooks et al., 1989; Ahmed et al., 1990; Cornell-Bell et al., 1990; Glaum et al., 1990; Cornell-Bell and Finkbeiner, 1991; Fukui et al., 1991; Neary et al., 1991; Nilsson et al., 1991; Gimpl et al., 1992, 1993). For some stimuli, a portion of the initial spike may depend on calcium influx (Jensen and Chiu, 1990; Marin et al., 1991a; Kastritsis et al., 1992).

By contrast, continued calcium influx is necessary to sustain biphasic/polyphasic responses. Removal of extracellular calcium eliminates the sustained component of responses evoked by acetylcholine (Brooks et al., 1989), ATP (Neary et al., 1991; Kastritsis et al., 1992), the A_1-purinergic receptor agonist 2-chloroadenosine (2-CA) (El-Etr et al., 1992), endothelin (Goldman et al., 1991; Marin et al., 1991a), histamine (Fukui et al., 1991), the α_1-adrenoreceptor agonist methoxamine (Iuvone et al., 1991), norepinephrine (Salm and McCarthy, 1990; Iuvone et al., 1991) or quisqualate (Glaum et al., 1990; Jensen and Chiu, 1990). In other cell types the sustained response follows internal calcium release and results from influx through nickel-sensitive, dihydropyridine-insensitive, voltage-independent plasma membrane channels (Penner et al., 1988). Since these channels open in response to empty internal calcium stores they are also called calcium release-activated channels (CRAC): CRACs are different from the calcium-activated calcium channels gated by the ryanodine receptor (Penner et al., 1993). Endothelin triggers sustained cytoplasmic calcium rises in astrocytes by tonically increasing plasma membrane calcium permeability consistent with CRAC activation (Marin et al., 1991a). Quisqualate (Glaum et al., 1990) and histamine (Fukui et al., 1991) induce glial calcium responses with similar features. However, internal store release may not always lead to a detectable sustained calcium influx. Low doses of endothelin or norepinephrine evoke an initial calcium spike without a subsequent sustained component (Salm and McCarthy, 1990; Goldman et al., 1991). In one experiment, phorbol ester exposure selectively blocked the internal release component but not the prolonged influx and the persistent plateau of acetylcholine-evoked calcium responses (Brooks et al., 1989).

In some polyphasic responses, the calcium level of the sustained component fluctuates in an oscillatory pattern (Figure 17-3B). Stimulus-evoked calcium oscillations persist in the absence of extracellular calcium, although the oscillations are usually less numerous, have smaller amplitudes (Charles et al., 1991; Kastritsis et al., 1992), and occur in a smaller fraction of cells (Cornell-Bell et al., 1990; Salm and McCarthy, 1990; Jensen and Chiu, 1991). Application of the inorganic calcium channel blockers nickel (Glaum et al., 1990; Jensen and Chiu, 1990; Marin et al., 1991a) or lanthanum (Fukui et al., 1991; Neary et al., 1991) also inhibit sustained calcium increases. Together, these results suggest that tonic calcium influx sustains the oscillation mechanism, although the oscillations themselves do not represent periodic calcium influx. The literature is replete with biochemical models of calcium oscillations; the details are beyond the scope of this chapter (for an excellent review see Fewtrell, 1993). Recent experiments suggest that the calcium ion itself can enhance or inhibit IP_3-activated release of internal calcium stores in a concentration dependent manner: the interaction may underlie the bistability necessary to generate calcium oscillations (Yao and Parker, 1992; Dupont and Goldbeter, 1993).

TEMPORAL ASPECTS OF GLIAL CALCIUM SIGNALING

Response Latency and Duration

The latency and duration of stimulus-coupled calcium responses vary considerably. Stimuli such as depolarizing potassium raise cytosolic calcium to maximal levels within seconds of application; calcium rapidly returns to baseline upon potassium removal (Figure 17-2A). Other stimuli such as GABA or kainate may show a significant delay between application and calcium response (Figures 17-2B, C) (Finkbeiner, 1991). Kainate- or GABA-induced calcium rises also grow more slowly, requiring several seconds to achieve peak levels (Dave et al., 1991; Finkbeiner, 1991). By contrast, glutamate or endothelin produces a rapid spikelike calcium rise, which peaks within a second or two of stimulation (Figure 17-3). Many GABA calcium responses ceased before agonist removal, whereas seconds of endothelin application raised cytosolic calcium for 20 to 30 minutes (Supattapone et al., 1989; Marin et al., 1991a) (Figures 17-2B and 17-3A). Cortical type-1 astrocytes similarly show GABA calcium responses, which develop slowly after a comparatively long latency (Nilsson et al., 1993), whereas mouse oligodendrocyte precursor cells exhibit rapid onset spikelike GABA responses (Kirchhoff and Kettenmann, 1992). GABA triggers responses mainly through the $GABA_A$ and partly through the $GABA_B$ receptor subtypes. The calcium rise results from internal store release and from influx through dihydropyridine-sensitive calcium channels opened by GABA-induced depolarization (Kirchhoff and Kettenmann, 1992; Nilsson et al., 1993).

Determinants of Response Pattern

Stimulus dose partly determines the shape of glial calcium responses. With increasing glutamate dose, response latency decreases and the amplitude of the initial spike increases (Ahmed et al., 1990). The frequency of evoked calcium oscillations increases until at high glutamate the predominant sustained response changes from an oscillatory pattern to a smooth plateau (Glaum et al., 1990; Cornell-Bell and Finkbeiner, 1991). Histamine responses are also dose-dependent: low histamine tends to evoke simple spikelike calcium transients, high histamine elicits a sustained component following the initial spike (Fukui et al., 1991). Increasing norepinephrine reduces the average latency calcium responses and shifts the predominant temporal pattern from a simple transient to a biphasic response (Salm and McCarthy, 1990). Low endothelin doses produce a transient calcium spike: at a slightly higher endothelin dose, a second sustained calcium rise appears briefly after termination of the initial spike. As the endothelin dose increases, the sustained component grows in amplitude and decreases in latency until it fuses with the initial spike to form a biphasic response (Goldman et al., 1991).

Receptor expression differences and receptor synergy also determine the shape of glial calcium responses. As an example of variable receptor expression, type-2 astrocytes respond to kainate, AMPA, and histamine more often than type-1 astrocytes (Fukui et al., 1991; Jensen and Chiu, 1991). However, type-1 astrocytes exhibit biphasic/polyphasic responses to glutamate, whereas type-2 astrocyte responses tend to be monophasic (Jensen and Chiu, 1991). In another example, α_1-adrenoreceptor density correlated with the fraction of rat cortical astrocytes showing phenylephrine calcium responses but did not correlate with response amplitudes (Shao and McCarthy, 1993). Interestingly, the receptor density varied widely among cultured astrocytes; even among astrocytes of the same lineage. Sometimes coapplication of two or more agonists produces calcium responses, which are more complex than the sum of the individual responses. For example, 2-chloroadenosine or the tachykinin receptor agonist, substance P, each elicits a transient calcium response (Delumeau et al., 1991). However, simultaneous substance P and 2-chloroadenosine application produces a nonadditive calcium rise that has a higher peak and significantly longer duration. Similarly, in mouse striatal astrocytes, somatostatin and methoxamine or 2-chloroadenosine stimulate transient calcium responses separately and a prolonged calcium response in combination (Marin et al., 1991b; El-Etr et al., 1992).

Acid/base status also plays a role in modulating ligand-induced calcium responses. Lowering extracellular pH substantially decreases ATP-evoked calcium influx in rat astrocytes (Neary et al., 1993). This may become important in certain pathological conditions which result in simultaneous tissue acidosis and ATP release (Neary and Norenberg, 1992). Certain stimuli, such as kainate and chemical depolarization, evoke simultaneous but independent changes in intracellular calcium and pH (Deitmer and Munsch, 1992; Deitmer et al., 1993).

SPATIAL ASPECTS OF GLIAL CALCIUM SIGNALING

Intracellular and Intercellular Calcium Waves

Fluorometric techniques reveal important spatial features to many glial calcium responses. Within a

single cell, calcium transients may appear in separate glial processes without involving the nucleus (S. Finkbeiner, unpublished observations). In other instances, calcium levels rise uniformly throughout the cytoplasm. Often glial calcium transients arise in one restricted part of a cell and propagate as a wave to other areas. The initial calcium spike of glutamate, quisqualate or histamine responses occurs first in the cell periphery and rapidly spreads to the nucleus within a second or two (Glaum et al., 1990; Cornell-Bell and Finkbeiner, 1991; Fukui et al., 1991). When viewed in sequence, the calcium rise appears to propagate from the edge of the cell to the center. This wave type occurs only once—during the initiation of a calcium response.

A second wave type may appear after the initial spike, during the sustained component of certain biphasic/polyphasic responses (Figure 17-4; Table 17-2). This intracellular calcium wave travels slowly with near-constant velocity and may recur multiple times. The initiation site and propagation path vary considerably from cell to cell, though recurrent waves frequently begin from the same location and propagate along the same path.

Intracellular calcium waves often cross cell boundaries, propagating through and between cells (Figure 17-5; Table 17-2). Intercellular calcium waves travel nearly 20 μm/s and may involve such large portions of a glial network that an exact measurement of the extent of some intercellular calcium waves is impossible. Glutamate-evoked intercellular waves depend on extracellular calcium: the incidence and spatial

extent of intercellular waves dramatically drops in the absence of extracellular calcium (Cornell-Bell et al., 1990). However, mechanically stimulated glial intercellular waves do not depend on extracellular calcium (Charles et al., 1991).

Spatial Organization and Agonist Dose

Stimulus dose may partly determine the spatial organization of calcium responses. In hippocampal astrocytes, increasing glutamate appears to organize calcium responses over progressively larger spatial domains: circumscribed asynchronous calcium transients occur within single cells at low doses; intracellular and intercellular calcium waves occur at higher doses (Cornell-Bell et al., 1990; Cornell-Bell and Finkbeiner, 1991). Increasing histamine dose changes cortical astrocyte responses from asynchronous calcium increases limited to cell processes into transients which propagate along cell processes toward the nucleus (Fukui et al., 1991).

Oscillations, Waves, and Mechanistic Models

The biochemical mechanism which propagates calcium waves is unknown. Generally, propagation theories incorporate diffusion in two dimensions into existing calcium oscillation models to create calcium waves. This approach fits observations in oocytes and some other cell types well (Berridge, 1993), however, several results in glial cells are difficult to reconcile with existing models. There may be important differences between glutamate-evoked calcium oscillations and waves. Calcium oscillations

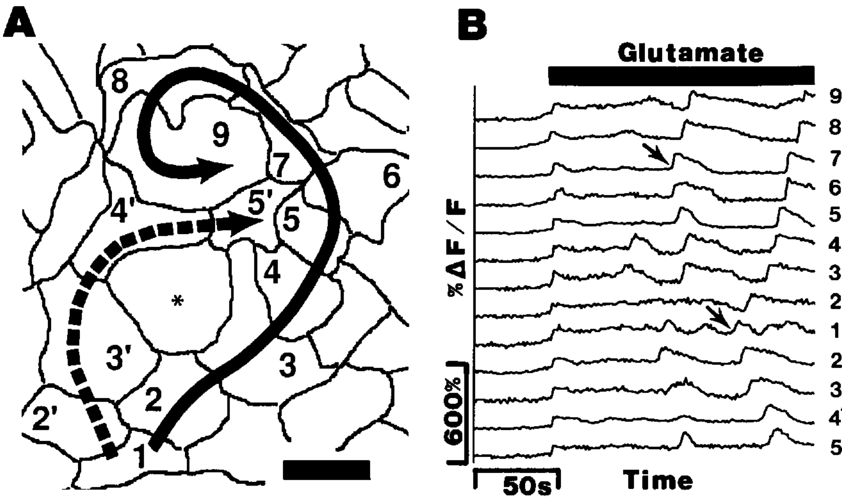

FIG. 17-5. Glial intercellular Ca^{2+} waves. (A) The outlined astrocyte labeled *1* initiates an intracellular Ca^{2+} wave, which propagates intercellularly (*arrow*). As the wave propagates into cells labeled *2* and *3'*, it encounters a natural barrier in the glial network, a glial cell that does not perpetuate the Ca^{2+} wave (*asterisk*). As the wave propagates around the nonparticipating cell, it effectively becomes two separate Ca^{2+} waves. Scale bar = 100 μm. (B) The Ca^{2+} responses of astrocytes from Figure *A* are depicted in the form of fluorescence-time course traces. Glutamate application (see addition bar at top of figure) first evokes a sharp Ca^{2+} transient, which appears as the initial spike in the trace of each astrocyte. In continued glutamate, some astrocytes initiate intracellular Ca^{2+} waves. Waves appear as abrupt rises in cytoplasmic Ca^{2+}, which peak early, plateau for 10 to 20 seconds, then return to baseline (e.g., *arrows*). Intercellular propagation appears as a regular succession of peaks in traces from adjoining astrocytes. For example, two intercellular Ca^{2+} waves are shown. The astrocyte labeled *7* initiates one intercellular Ca^{2+} wave (*first arrow*). The intercellular wave propagates in two directions: through cells labeled *8* and *9* and also through cells labeled *6* and *5* (the apparent involvement of cells labeled *3* and *4* is actually another Ca^{2+} wave which is initiated in cell *3* and propagates into cell *4*). As the wave propagates through the neighboring cells, the stereotypical cytoplasmic Ca^{2+} rise occurs with the peak phase shifted by a time interval that is proportional to the distance the wave traveled. The second intercellular wave (and the subject of Figure *A*) is initiated by the astrocyte labeled *1* (*second arrow*). [Adapted from Finkbeiner (1992), with permission.]

appear quickly after the initial spike, have a typical temporal pattern with a relatively slow rise and fall and an amplitude that is usually less than the initial spike. For a given cell, repeated stimulation often evokes nearly identical oscillatory responses and a wide variety of stimuli evoke similar, though not identical, oscillations. Early in an oscillatory response, calcium appears to rise and fall uniformly in all regions of a cell. As the oscillations continue, rises often become nonuniform: one subsection of the cell appears to lead the rest. Although the temporal profile of the calcium response maintains the original oscillatory shape, peaks of the oscillation sampled within the cell become phase-shifted, resulting in a wavelike appearance to the calcium rise. However, these "waves" propagate rapidly (30 to 60 μm/s); much quicker than intercellular calcium waves (15 to 20 μm/s).

By contrast, intercellular calcium waves are less common than oscillations and appear episodically rather than periodically following the initial spike. The shape differs from oscillations in that waves have an abrupt onset with a rapid rise to a peak amplitude similar to the initial spike. The duration is invariably longer than a typical oscillation such that the transient has a spike and plateau shape rather than the more sinusoidal shape of an oscillation. Recurrent calcium waves during a single stimulation are uncommon, and repeated stimulation rarely elicits recurrent waves.

Observations of apparent interactions between calcium oscillations and waves also do not fit well with current oscillation models. Occasionally, cells that propagate intercellular calcium waves will neighbor cells undergoing cytosolic calcium oscillations. In such cases, the oscillations often decrease in amplitude or frequency as the wave propagates nearby and may recur once the wave passes (Cornell-Bell and Finkbeiner, 1991). Curiously, adjoining astrocytes exhibiting calcium oscillations do not detectably coordinate responses and astrocytes, which organize to propagate mechanically stimulated calcium waves,

frequently show asynchronous calcium oscillations after the wave passes (Charles et al., 1991).

Although the details of calcium wave propagation are unclear, the data suggest several conclusions. The signal underlying wave propagation travels intracellularly. In support, calcium wave velocity and propagation direction are independent of the flow of superfusate, and calcium waves propagate around, rather than through, natural or artificial interruptions in the glial network (Enkvist and McCarthy, 1992; Finkbeiner, 1992). Short-range reaction-diffusion drives propagation rather than long-range diffusion, since the wave velocity remains constant over long distances (Finkbeiner, 1992). Depletion of IP_3-sensitive internal calcium stores with thapsigargin abolishes glutamate- or mechanically induced waves, suggesting IP_3-induced calcium release is necessary to permit propagation (Charles et al., 1993). Finally, the signal travels from cell to cell by gap junctions. Gap junction closure using cellular acidification, protein kinase C activation, or the gap junction blockers, octanol or halothane, sharply reduces intercellular propagation (Enkvist and McCarthy, 1992; Finkbeiner, 1992). In the case of octanol and halothane, calcium waves travel within cells, but are unable to travel between cells.

One important but unproven assumption holds that all calcium waves propagate by the same mechanism regardless of the initial stimulus. Although the assumption is probably valid, there are differences between glutamate-evoked and mechanically stimulated glial calcium waves. Most importantly, mechanically stimulated waves propagate unaffected in calcium-free media, whereas we have yet to observe a glutamate-evoked intercellular wave under the same conditions. Mechanically stimulated calcium waves also differ in that the wave generally spreads concentrically outward to involve most or all of the surrounding visible cells. Glutamate-induced waves generally involve fewer cells and may propagate along convoluted paths. In this regard, mechanically induced calcium waves are similar to waves evoked by kainate or sodium-free media (Finkbeiner, 1991). Mechanical stimulation may trigger the metabolism of other plasma membrane lipids besides phosphatidylinositol bisphosphate, such as sphingosylphosphorylcholine. Certain sphingosine metabolites trigger the release of both the IP_3-sensitive calcium pool as well as another guanosine triphosphate (GTP)-sensitive calcium pool in a permeabilized cell preparation (Gill et al., 1992). However, it is difficult to imagine how this difference could account for propagation differences many micrometers from the stimulation site.

What might account for the differences between calcium oscillations and calcium waves and the interactions between cells exhibiting the response types? One idea posits two IP_3-sensitive calcium pools, one immediately beneath the plasma membrane, the second deep within the cell (Berridge, 1992). Upon stimulation, IP_3 rises near the membrane and causes an efflux of calcium from the pool proximal to the membrane without releasing calcium from the deep pool. Instead, the empty proximal pool results in calcium release-activated channel activation and transmembrane calcium influx, which charges the deep and proximal pools (Penner et al., 1993). Oscillations begin when deep pools become calcium-loaded, sensitizing the IP_3 receptors so that ambient IP_3 levels are sufficient to trigger release. The negative and positive feedback of the calcium ion on the IP_3 receptor generates the oscillation (Amundson and Clapham, 1993). Calcium oscillations could occur uniformly throughout a cell or appear wavelike, as calcium release at one point diffuses to influence IP_3-gated calcium release nearby. However, the temporal pattern should not change fundamentally and should always resemble an oscillation. In this formulation, the deep store largely resides in the perinuclear area and tapers near the cell periphery. Therefore, the lack of synchrony among neighboring oscillators could result from impedance mismatch: the concentration of the biochemicals underlying the calcium cycle would not achieve sufficient concentrations near the periphery to diffuse through gap junctions and impose a rhythm on a neighboring cell. True calcium waves might occur when loaded calcium stores near the plasma membrane participate. They too may need to load calcium sufficiently to resensitize the IP_3 receptors to enable the pool to release calcium. Involvement of two pools could explain why the amplitude and duration of waves is greater than oscillations. A subplasma membrane pool would also abut gap junctions at sites of cell-cell contact and might be expected to facilitate intercellular wave propagation. Mechanical stimulation may be more effective at triggering the release of proximal as well as deep stores and thus evoke a wave without calcium loading. This model fails to explain how a wave propagating through one cell could inhibit the oscillations of a neighbor without directly causing a detectable calcium change in the oscillating cell.

Another proposal suggests that the transition between oscillation and wave occurs when intracellular calcium buffering transiently decreases. This could result from transient inhibition or reversal of the plasma membrane sodium-calcium exchanger, inhibition of calcium-ATPases on internal stores, occupation of cytoplasmic calcium binding sites or mod-

ulation of the number or capacity of internal calcium stores. The change would necessarily be transient, since calcium oscillations can precede and follow calcium waves. A decrease in calcium buffering would allow a given quantity of calcium flowing into the cytoplasm to achieve a higher concentration and exert more influence on calcium-sensitive structures. In effect, a sufficient decrease could enhance calcium diffusion and raise resting levels of cytoplasmic calcium. Oscillations would result when IP_3 release sites are functionally isolated from one another by calcium buffering: waves would arise when the internal stores are linked by enhanced two-dimensional calcium diffusion due to buffering capacity reduction. A buffering decrease would also increase the amplitude and duration of calcium waves compared with oscillations, as seen experimentally. It is difficult to explain mechanically stimulated waves with this model and it also fails to explain how calcium waves could inhibit calcium oscillations.

SECOND-MESSENGER CROSSTALK

Glial calcium changes influence a host of second-messenger systems and ion channels, which directly or indirectly feedback to modulate calcium signaling (see Chapter 34, this volume). The calcium ion is part of a web of second-messenger and ion channel crosstalk, which needs to be understood to predict the full response of glial cells *in vivo* (Figure 17-6).

A discussion of all calcium-regulated glial functions is beyond the scope of this chapter (for review see Finkbeiner, 1993). However, a few examples will serve to illustrate how crosstalk may importantly alter glial calcium responses. Receptor-stimulated inositol turnover often leads to protein kinase C activation in addition to cytoplasmic calcium increases. Protein kinase C can feedback to inhibit the receptor-event that led to its activation. Potent protein kinase C activators, phorbol esters, block calcium responses to norepinephrine or the muscarinic receptor agonist carbachol (Orellana et al., 1985; Pearce et al., 1988), quisqualate and glutamate (Jensen and Chiu, 1990; Finkbeiner, 1991), endothelin and the proteolytic enzyme thrombin (Tas and Koschel, 1990; Lin et al., 1992), and histamine (Fukui et al., 1991). In some cases, phorbol esters alter specific components of calcium responses. Phorbol esters block the initial calcium spike, but not the subsequent sustained response to quisqualate (Glaum et al., 1990) or to acetylcholine (Brooks et al., 1989). In support of a specific protein kinase C-mediated effect, inactive phorbol ester analogues do not alter calcium responses to norepinephrine (Pearce et al., 1988) or

Second-messenger crosstalk and glial Ca^{2+}, showing some of the known interactions between glial Ca^{2+} and other glial signaling systems. *Arrows with solid heads* show activation or production; *arrows with hollow heads* show release; *arrows with solid heads terminating in a perpendicular dash* indicate inhibition and arrows terminating in a cross show reduction. A *question mark* indicates uncertainty about the existence or basis of interaction. *ER*, endoplasmic reticulum; *IP_3*, inositol-1,4,5 trisphosphate; *PLC*, phospholipase C; *DAG*, diacylglycerol; *PKC*, protein kinase C; *AC*, adenyl cyclase; *cAMP*, cyclic adenosine monophosphate; *PDE*, phosphodiesterase; *cGMP*, cyclic guanine monophosphate; *AA*, arachidonic acid; *PLA_2*, phospholipase A_2; *cycloox*, cyclooxygenase; *lipox*, lipoxygenase.

thrombin (Tas and Koschel, 1990). The effect seems specific to stimuli that activate receptors coupled to phospholipase C, since phorbol esters do not inhibit spontaneous calcium spikes or agonist-induced calcium responses to kainate (Enkvist et al., 1989a; Jensen and Chiu, 1990).

Arachidonic acid- and calcium-mobilizing pathways interact in several ways. Glial calcium rises stimulate phospholipase A_2 to mobilize arachidonic acid and cyclooxygenase and lipoxygenase metabolites (Shirazi et al., 1989; Bruner and Murphy, 1990; Ishizaki and Murota, 1991). One way calcium rises may activate phospholipase A_2 is through protein kinase C-mediated phosphorylation of the endogenous phospholipase A_2 inhibitor, lipocortin (Murphy et al., 1985; Shirazi et al., 1989). Subsequently, arachidonic acid mobilization modulates glial calcium responses. Arachidonic acid evokes a slow cytoplasmic calcium rise in hippocampal, cortical, and striatal astrocytes (Delumeau et al., 1991; Finkbeiner, 1991) and activates a voltage-independent, nonselective calcium channel in rat oligodendrocytes (Soliven et al., 1993). Arachidonic acid may also modulate glial calcium indirectly. For example, arachidonic acid inhibits glial glutamate uptake, causing extracellular glutamate to accumulate sufficiently to activate glutamate receptors (Marin et al., 1991b; El-Etr et al., 1992; van den

Pol et al., 1992). *In vitro,* substance P or 2-chloroadenosine appears to potentiate methoxamine-evoked calcium responses by activating glutamate receptors through arachidonic-acid mediated inhibition of glutamate uptake (Marin et al., 1991b; El-Etr et al., 1992). Arachidonic acid also activates a glial potassium channel, which causes membrane hyperpolarization and thus enhances the electrochemical gradient for transmembrane calcium entry (Delumeau et al., 1991). These interactions may be particularly important *in vivo* where neurotransmitter and neuropeptide are often released at the same synapse (Cooper et al., 1991).

THE FUTURE: A CALCIUM-BASED GLIAL SIGNALING SYSTEM

Too little is known of calcium-regulated glial processes to guess how particular glial calcium response patterns might be translated into specific physiological responses. However, features of calcium responses, which glia exhibit singly and as a network, could form the basis for a calcium-based long-range signaling system *in vivo.* As components of the network, glial cells are capable of dependably encoding information such as the type and intensity of a stimulus. Glia are capable of encoding stimulus type through the combination of receptors that a particular cell expresses and through the percentage of cells that respond to a particular ligand (McCarthy and Salm, 1991; Nilsson et al., 1991; van den Pol et al., 1992; Deecher et al., 1993; Finkbeiner, 1993; Shao and McCarthy, 1993). Consequently, some stimuli produce monophasic responses, others biphasic responses, still others produce polyphasic responses with an almost infinite set of possible patterns. Glia can encode stimulus intensity through changes in the temporal pattern, such as oscillation frequency, or in the spatial extent of the response. Glia also show precisely reproducible responses (Finkbeiner, 1993). The property, called *fingerprinting,* refers to the fact that a given agonist tends to evoke reproducible calcium response patterns in a particular glial cell though the response patterns may differ widely between cells (Rooney et al., 1989). As a network, glia *in vitro* transmit calcium signals nondecrementally over long distances via propagating intercellular calcium waves. The network has a specific circuitry determined by the level of intercellular gap junction coupling (see Chapter 19, this volume). Glial networks also show plasticity, since glial connectivity can rapidly and reversibly respond to neuronally released substances which regulate gap junctional coupling (Enkvist and McCarthy, 1992). Other reviews discuss the plausibility of glial involvement in neural information processing (Smith, 1992; Finkbeiner, 1993).

Nearly all glial calcium response data comes from *in vitro* culture systems; however, recent discoveries suggest that glial calcium signaling occurs *in vivo.* *First,* glia often respond preferentially to neurotransmitters, neuropeptides, or other stimuli present in the particular brain region from which the cells are cultured (Somogyi et al., 1990; van den Pol et al., 1992). *Second,* glial cells *in situ* express and translate mRNA for a variety of ion channels and neurotransmitter receptors (Matute and Miledi, 1993). For example, Bergmann glia express glutamate receptors in processes adjacent to synapses, which release glutamate (Somogyi et al., 1990). *Third,* selective electrical stimulation of hippocampal neurons in organotypic slices elicits astrocytic calcium waves, presumably through local transmitter release (Dani et al., 1992). Organotypic slices are cultured brain slices, which retain some *in vivo* anatomical relationships. *Fourth,* acutely excised rat optic nerve astrocytes exhibit calcium spiking, which reflects the level of neuronal activity. *In situ* calcium responses to the exogenously applied glutamate analogues AMPA, ACPD, and kainate resembled responses obtained *in vitro* except no calcium waves were seen (Kriegler and Chiu, 1993).

CONCLUSIONS

In many ways glial control of intracellular calcium is similar to other cell types: energy-dependent pumps and exchangers maintain a steep calcium concentration gradient between the cytosol and the extracellular solution or internal calcium stores. Similar to other cells, stimuli activate calcium influx through several plasma membrane calcium channel types, release calcium from internal stores or do both. However, the sheer number of stimuli to which glia respond and the temporal and spatial complexity of calcium responses are unequaled. Although the significance of the particular patterns is unknown, response characteristics suggest a calcium-based glial signaling system, which is both robust and specific. Yet, many questions remain unanswered. Exactly what comprises glial calcium stores and how are they regulated? What, systems do glia possess to translate complex calcium response patterns into specific physiological responses? What is the neurobiological significance of astrocytic calcium wave propagation? Finally, what glial calcium signaling occurs *in vivo* and what is its purpose?

This work was supported in part by Public Health Service grant 2 T32 GM07205-16.

18 Modulation of glial potassium, sodium, and chloride activities by the extracellular milieu

KLAUS BALLANYI

Activity in the central nervous system is accompanied by movements of ions and water across neuronal membranes that modify the composition of the adjacent extracellular space. The interposition of glial cells between the neurons, and the geometry and membrane properties of these cells, have led to the suggestion that an important role of glial cells is to contribute to the homeostasis of the extracellular fluid (Orkand et al., 1986; Coles, 1989; Walz, 1989). It is well known that enhanced neuronal activity is accompanied by transient elevations of extracellular K^+ activity (aK_e) (Somjen, 1979; Chapter 26, this volume). Such alterations of aK_e can perturb neuronal functions (Sykova, 1983). Measurements of glial membrane potentials, aK_e, and extracellular space volume during physiological or electrical stimulation of neurons have established the idea that glial cells are responsible for K^+ buffering in the brain. Quantitative aspects of these relations between neuronal and glial responses are given in Chapters 11, 26, 31, 47, and 62 (see also Dietzel et al., 1989).

Until intracellular ion-sensitive microelectrodes were used, it was not clear to what extent K^+ uptake might affect the intracellular ion milieu of glia. Double-barreled, ion-sensitive microelectrodes monitor membrane potentials and, simultaneously, cellular ion activities (Ammann, 1986). This gives information about relevant physiological processes since the transmembraneous gradients of ion activities, rather than those of total ion concentrations, determine equilibrium potentials for different ions and, therefore, membrane potentials and cellular functions.

This chapter concentrates on the intracellular activities of K^+, Na^+, and Cl^- (aK_i, aNa_i, aCl_i), since the homeostasis of these ions is essential for a variety of glial properties, including membrane potential, cell volume, and K^+ buffering. Most of the data on modulation of glial aK_i, aNa_i, and aCl_i stem from *in vitro* studies on (1) astrocytes in brain slices, (2) cultured astrocytes or oligodendrocytes, (3) glial cells of the medicinal leech, and (4) pigment epithelial glial cells in the bee retina (see Table 18-1 for references).

RELATION BETWEEN INTRACELLULAR ION ACTIVITIES AND ION CONTENT

A quantitative comparison of glial ion activities and ion content in the bee retina indicates that intracellular K^+, Na^+, and Cl^- are freely dissolved in the cytosol (Coles et al., 1986; Orkand et al., 1986). A similar situation is believed to exist in glial cells of other nervous tissues. Accordingly, recordings with microelectrodes, selective for these ions, can also be labeled in free concentrations, by dividing activities by an activity coefficient (γ) of approximately 0.7 (Ammann, 1986; Orkand et al., 1986). Changes in ion activities are due only to transmembrane fluxes of ions or water, not to exchange with binding sites. This is in contrast to intracellular Ca^{2+} or H^+, which are predominantly bound or sequestered (Coles, 1989; Chapter 17, this volume).

LIMITATIONS OF MEASUREMENTS OF INTRACELLULAR ION ACTIVITIES

The quantitative determination of intracellular ion activities can, for example, suffer from junction potentials on the reference barrel of the ion-sensitive microelectrodes (Orkand et al., 1986; Coles et al., 1989) or from interference of other cellular ions with the ion-sensitive ligands (Ammann, 1986). Using the classical Corning ion-exchanger as a K^+ sensor, measurements of aK_i can be distorted by a high aNa_i or by intracellular substances with a quaternary ammonium-based structure like acetylcholine or serotonin (Ammann, 1986). In glial cells of the medicinal leech (Schlue and Wuttke, 1983) or of the bee retina (Coles and Orkand, 1983), resting aK_i

appears to be up to 20% higher when measured with the Corning exchanger instead of a neutral carrier, which is highly selective for K^+. Even greater discrepancies have been reported for resting levels of aK_i in glial cells of the frog spinal cord (Bührle and Sonnhof, 1983). In astrocytes of guinea pig olfactory cortex (Ballanyi et al., 1987), aK_i was monitored with Corning microelectrodes, which, due to the small size of their tips, had only a negligible sensitivity to quaternary ammonium ions (Ammann, 1986). A precise determination of glial aCl_i is hindered by interferences from intracellular anions like HCO_3^-. In low Cl^- solutions, such anions produce an electrode signal corresponding to an apparent aCl_i of 0.5–4 mM (Ballanyi et al., 1987; Kettenmann, 1987; Coles et al., 1989; Hoppe and Kettenmann, 1989a; Ballanyi and Schlue, 1990) (Figures 18-2 and 18-3). In contrast, interference of aNa_i measurements from cellular cations like Ca^{2+} is assumed to be rather small (Coles and Orkand, 1985; Ballanyi et al., 1987). Intraglial Na^+ in Na^+-free solutions can decrease to an apparent aNa_i of less than 1 mM in cultured mouse oligodendrocytes (Ballanyi and Kettenmann, 1990).

RESTING LEVELS OF aK_i AND aNa_i

Despite differences in the composition and ionic strength of the superfusion media, the K^+ and Na^+ gradients and, therefore, the equilibrium potentials for K^+ and Na^+ (E_K, E_{Na}), as derived from the Nernst equation, are similar in glial cells of different preparations (Table 18-1). Glial membrane potential (E_m) is close to E_K (Figure 18-2) which is in line with the assumption that, under resting conditions, K^+ channels in these cells contribute to a much higher degree to membrane conductance than Na^+ and/or Ca^{2+} channels (Orkand et al., 1966). It appears that aK_i is lower and aNa_i is higher in glial cells than in neurons, as measured in preparations that allow recordings from both types of brain cells (Coles and Tsacopoulos, 1979; Coles and Orkand, 1983, 1985; Ballanyi et al., 1987; Grafe and Ballanyi, 1987; Ballanyi and Schlue, 1990; Dörner et al., 1990) (Figure 18-1).

RESTING LEVEL OF aCl_i

In several types of glial cells *in situ*, aCl_i indicates a passive distribution of Cl^- (Bührle and Sonnhof, 1983; Ballanyi et al., 1987; Ballanyi and Schlue, 1990; Wuttke, 1990). This means that E_{Cl} is almost identical to E_m and aCl_i can rapidly follow changes of glial E_m (Figures 18-2 and 18-3). Such passive Cl^- movements require a significant Cl^- conductance as has been reported for leech neuropile glial cells (Schlue and Walz, 1984) and for a subpopulation of cultured oligodendrocytes of mouse spinal cord (Kettenmann, 1987). Inwardly directed Cl^- pumps seem to provide an aCl_i in retinal glial cells (Coles et al., 1989) and in a major population of cultured mouse oligodendrocytes (Hoppe and Kettenmann,

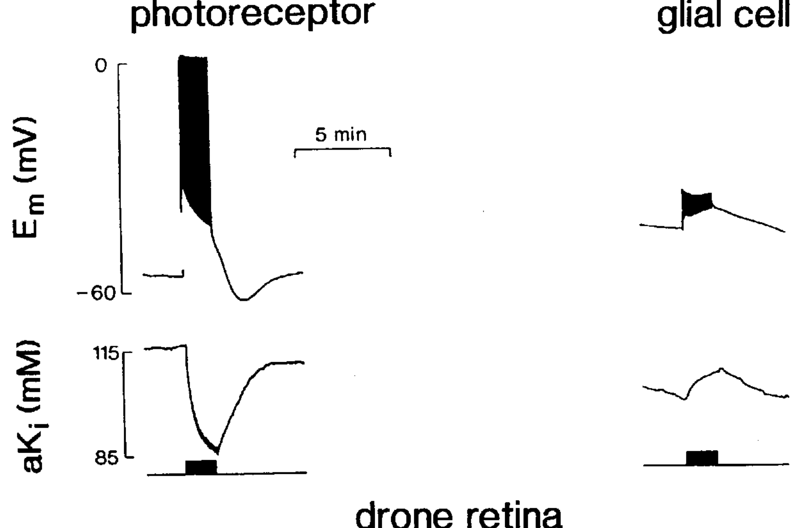

FIG. 18-1. Light-evoked electrical responses and changes in intracellular K^+ activity (aK_i) in the drone retina. The top trace is the membrane potential (E_m) of a photoreceptor (*left traces*) and a glial cell (*right traces*) recorded by the reference barrel of a double-barreled microelectrode. The *middle trace* is the difference in potential between the top trace and that of the barrel containing the K^+ sensor and gives aK_i. The *solid bars* on the lowest trace indicate when the retina was stimulated with 20-ms flashes of light at 1 Hz for 90 seconds. Note that aK_i decreases in the photoreceptor and increases in the glial cell, although both types of brain cells are depolarized in response to such stimulation. [From Orkand et al. (1986), with permission.]

1989a, 1989b), which is 2 to 5 mM higher than expected from a passive Cl^- distribution (Kettenmann, 1987) (Figure 18-3). In contrast to these reports on a rather low intracellular Cl^-, aCl_i is up to 40 mM above electrochemical equilibrium in cultured mouse astrocytes, indicating the activity of an inwardly directed Cl^- pump (Kettenmann, 1987) (Figure 18-3). In summary, the data on aCl_i suggests that Cl^- pumps might be expressed in a variety of glial cells. Their activity, however, is possibly masked to a more or less degree by short-circuiting Cl^- conductances, as has been demonstrated for mammalian skeletal muscle (Aickin et al., 1989).

K^+-DEPENDENT MODULATION OF aK_i, aNa_i, AND aCl_i

Excitatory synaptic activity results in an opening of transmitter- and voltage-gated neuronal ion channels. This evokes a Na^+ influx and a K^+ efflux, which can lead to a rise of neuronal aNa_i and a concomitant fall of aK_i (Orkand et al., 1986; Grafe and Ballanyi, 1987; Dörner et al., 1990) (Figure 18-1). As a result of such a neuronal K^+ release, aK_e can increase by several mM (Somjen, 1979; Sykova, 1983; Chapter 26, this volume). This induces a depolarization of the adjacent glial cells which is due

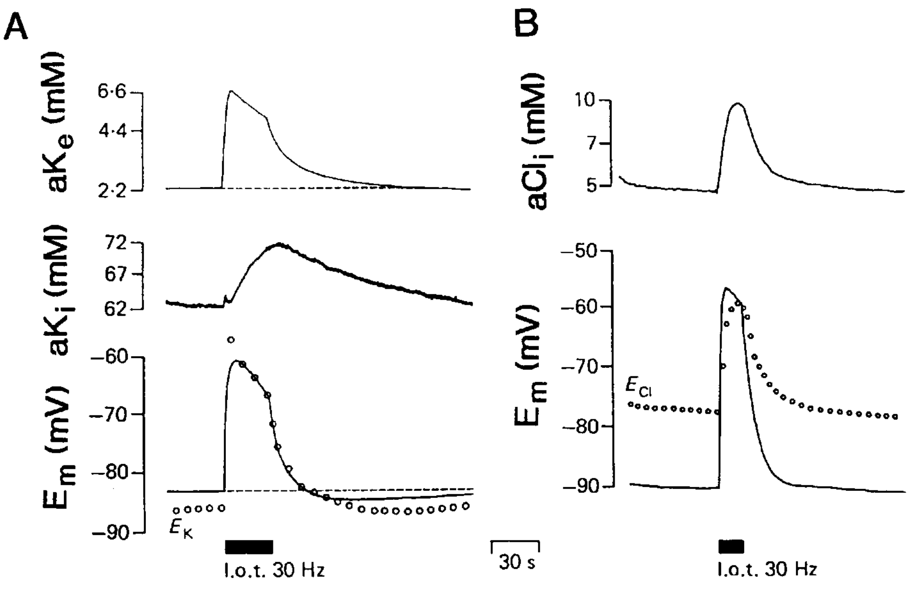

FIG. 18-2. (**A, B**) Electrical stimulation of the lateral olfactory tract (*l.o.t.*) of guinea pig olfactory cortex slices leads to increases of the intracellular activities of K^+ (aK_i) and Cl^- (aCl_i) in astrocytes. During the depolarization, the equilibrium potentials of K^+ (E_K) and Cl^- (E_{Cl}), as calculated using the measured values of aK_i and aCl_i, are almost identical to the membrane potential (E_m). The discrepancy between E_m and E_K before and after the stimulation indicates a contribution of Na^+ and/or Ca^{2+} conductances to resting E_m. The apparent discrepancy between E_{Cl} and E_m under resting conditions is due to interference of the Cl^- sensor from unknown intracellular anions. [From Ballanyi et al. (1987), with permission.]

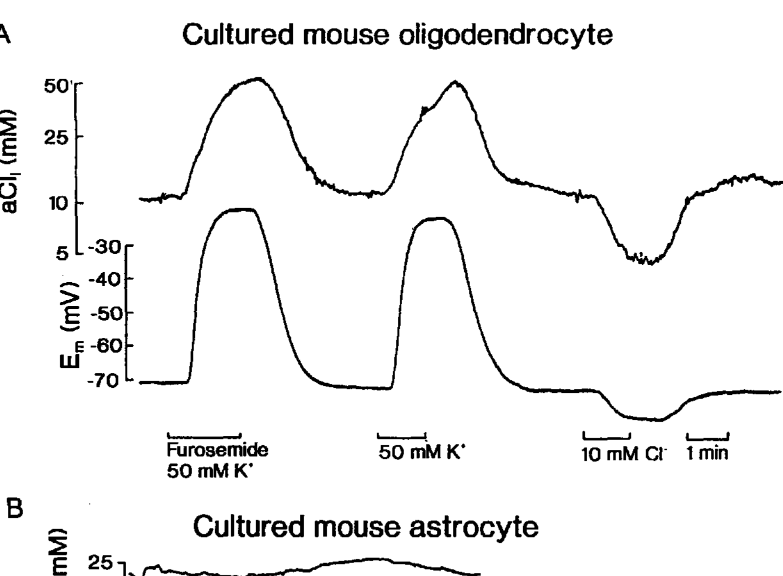

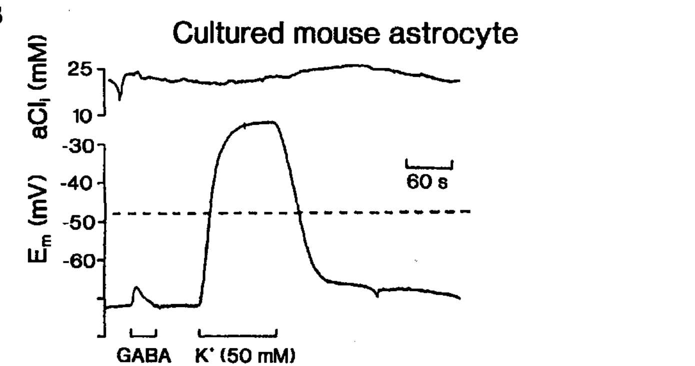

FIG. 18-3. (A) Transmembrane Cl^- movements in an oligodendrocyte, induced by changes in the extracellular concentration of K^+ ($[K^+]_0$) or Cl^- ($[Cl^-]_0$). *Top trace* displays intracellular Cl^- activity (aCl_i); *bottom trace*, membrane potential (E_m). Furosemide (10^{-4} M) in elevated $[K^+]_0$ and low $[Cl^-]_0$ (10 mM) were applied by exchange of the bathing fluid. The apparent hyperpolarization of E_m in low $[Cl^-]_0$ was caused by interference of this solution with the reference electrode. (B) aCl_i of an astrocyte. GABA (1 mM) and elevated $[K^+]_0$ were applied as indicated by the bars. The Cl^- equilibrium potential was calculated based on the measurement of aCl_i at the beginning of the trace and is indicated by the broken line. Note that the K^+-evoked depolarization leads to massive increases of aCl_i in the oligodendrocyte, but not in the astrocyte. [From Kettenmann (1987), with permission.]

to their high K^+ conductance (Orkand et al., 1966; Chapters 11 and 47, this volume). The K^+-induced glial depolarizations are accompanied by an increase of aK_i (Figures 18-1 and 18-2). Such glial K^+ uptake was originally demonstrated for Müller glial cells in the frog retina (Mori et al., 1976) and has been confirmed for glial cells in a variety of other nervous tissues (Coles and Tsacopoulos, 1979; Kettenmann et al., 1983; Schlue and Wuttke, 1983; Ballanyi et al., 1987; Walz, 1992). During these glial depolarizations, E_m is almost identical to E_K, which can precisely be determined when aK_e and aK_i are measured simultaneously (Figure 18-2) (see also Kettenmann et al., 1983; Kettenmann, 1987). The K^+-dependent increases of aK_i are mirrored by decreases of aNa_i as originally observed in the bee retina (Coles and Orkand, 1985) and later also in glial cells of mammals (Ballanyi et al., 1987; Ballanyi and Kettenmann, 1990) and of the medicinal leech (Ballanyi and Schlue, 1989). In the majority of glial cells investigated, the K^+-evoked changes of aK_i and aNa_i are accompanied by an increase of glial aCl_i (Ballanyi et al., 1987; Kettenmann, 1987; Ballanyi and Schlue, 1989, 1990; Coles et al., 1989; Hoppe and Kettenmann, 1989a; Wuttke, 1990) (Figures 18-2 and 18-3). The magnitude of the K^+-related changes of aK_i, aNa_i and aCl_i depends on the amplitude and duration of the activity-induced rises of aK_e and, therefore, glial depolarizations.

MECHANISMS OF K^+-EVOKED CHANGES OF aK_i, aNa_i, AND aCl_i

Donnan-like Influx of Potassium Chloride

A major portion of glial K^+ uptake appears to occur via K^+ and Cl^- influx through (Ba^{2+}-sensitive) K^+ and through Cl^- channels (Orkand et al., 1986; Ballanyi et al., 1987; Kettenmann, 1987; Walz, 1989). These transmembrane KCl fluxes can be explained by a passive Donnan-like redistribution of K^+ and Cl^-. During the initial phase of extracellular K^+ elevation, K^+ enters the glial cells when E_K is more positive than E_m, which is "clamped" to a more negative value by the Cl^- conductance (see also Chapter 26). Cl^- then enters the cells to establish a passive Cl^- distribution (Ballanyi et al., 1987; Kettenmann, 1987; Coles et al., 1989). In glial cells which are assumed to have a rather low Cl^- conductance at resting E_m, it was proposed that activation of voltage-dependent Cl^- conductances, as originally found in cultured rat astrocytes (Bevan et al., 1985), might mediate such passive Cl^- influx at depolarized potentials

(Kettenmann, 1987; Coles et al., 1989; Walz, 1989). However, even K^+-evoked depolarizations of up to 50 mV amplitude had almost no effect on aCl_i in cultured mouse astrocytes (Kettenmann, 1987; cf. Chapter 13).

Glial Swelling Evoked by Passive Potassium Chloride Influx

For osmotic balance, a passive accumulation of KCl, as described above, needs to be accompanied by an equimolar influx of water into the glial cells. This should lead to cell swelling (Orkand et al., 1986; Ballanyi and Grafe, 1988). Electrophysiological measurements of volume changes in leech neuropile glial cells have indeed shown that K^+-evoked swelling and shrinkage can be explained by a Donnan-like redistribution of KCl and water (Ballanyi and Grafe, 1988; Ballanyi et al., 1990; Wuttke, 1990) (Figure 18-4). Similar results were recently reported for cultured mouse astrocytes (Walz, 1992). However, if a passive KCl and water uptake were the only mechanism for glial K^+ accumulation, only a small increase of aK_i would be expected, since the amount of KCl which is passively taken up by the glia is isotonic. If K^+ was the only intracellular cation, such K^+ accumulation would not affect aK_i at all as the K^+ influx would completely be compensated by the accompanying influx of water (for details, see Orkand et al., 1986; Ballanyi and Grafe, 1988). Such glial swelling has a diluting effect on aNa_i which is assumed to be responsible for a major portion of the K^+-induced decrease of aNa_i (Wuttke, 1990). However, in various types of glial cells, the K^+-evoked decrease of aNa_i is bigger than that expected from a dilution as induced by cell swelling (Ballanyi and Kettenmann, 1990) (Figure 18-5). These considerations suggest that a different mechanism, involving an outward transport of Na^+, coupled to an inward transport of K^+, is involved in K^+-evoked glial K^+ uptake.

Sodium/Potassium Pump

The glial Na^+/K^+ pump is activated by excess of extracellular K^+ (Walz, 1989; Chapter 16, this volume). This becomes evident, when channel-mediated KCl uptake is inhibited by Ba^{2+}, which blocks glial K^+ conductances (Ballanyi et al., 1987; Ballanyi and Schlue, 1990). In the presence of Ba^{2+}, the remaining K^+-induced increases of aK_i (and the corresponding decreases of aNa_i) are blocked after addition of ouabain, which is an inhibitor of the Na^+/K^+ pump (Ballanyi et al., 1987; Grafe and Ballanyi, 1987). Similarly, ouabain blocked a slowly developing component of the K^+-evoked aNa_i decrease in cultured oligodendrocytes (Ballanyi and Kettenmann, 1990) (Figure 18-5).

It is assumed that during each pump-cycle, more Na^+ than K^+ is transported across the membrane (Ballanyi et al., 1987; Kettenmann, 1987; Walz, 1989; Chapter 16, this volume). Therefore, the electrogenic Na^+/K^+ pump tends to hyperpolarize the glial cells. For electroneutrality and osmotic balance, the net efflux of Na^+ needs to be compensated by a passive efflux of Cl^- and water. Accordingly, aCl_i has been demonstrated to decrease during Na^+/K^+ pump-evoked hyperpolarizations in astrocytes (Ballanyi et al., 1987). The Na^+/K^+ pump, therefore, contributes to the regulation of cell volume (Ballanyi and Grafe, 1988).

Na^+-K^+-$2Cl^-$ Cotransport

Measurements of ion fluxes with radiotracer methods have suggested that a substantial portion of K^+-related glial K^+ and Cl^- accumulation might be mediated by a Na^+-K^+-$2Cl^-$ cotransport (Walz, 1987, 1989, Chapter 13, this volume). However, a contribution of such K^+ transport to K^+-induced glial Cl^- uptake is not evident from measurements with ion-sensitive microelectrodes, since the increases of aCl_i are not affected by selective transport inhibitors such as furosemide and bumetanide (Kettenmann, 1987; Ballanyi and Schlue, 1990) (Figure 18-3). These inhibitors, however, blocked the recovery of aCl_i after exposure to solutions with a low Cl^- concentration. This indicates that Na^+-K^+-$2Cl^-$ cotransport is involved in the processes contributing to the maintenance of resting aCl_i (Hoppe and Kettenmann, 1989a). A detailed view of the function of anion transporters (and channels) in glia is given in Chapter 13.

Spatial Buffering

In addition to the K^+ uptake mechanisms described above, "spatial buffer" currents contribute to K^+ redistribution in the central nervous system in particular when activity-related increases of extracellular K^+ around the glia are not uniform (Orkand et al., 1966). This glial K^+ transfer might also affect aK_i, aNa_i, or aCl_i (Orkand et al., 1986). Spatial buffering is particularly relevant in certain central nervous system regions like the retina as discussed, for example, in Chapters 11, 31, 47, and 62.

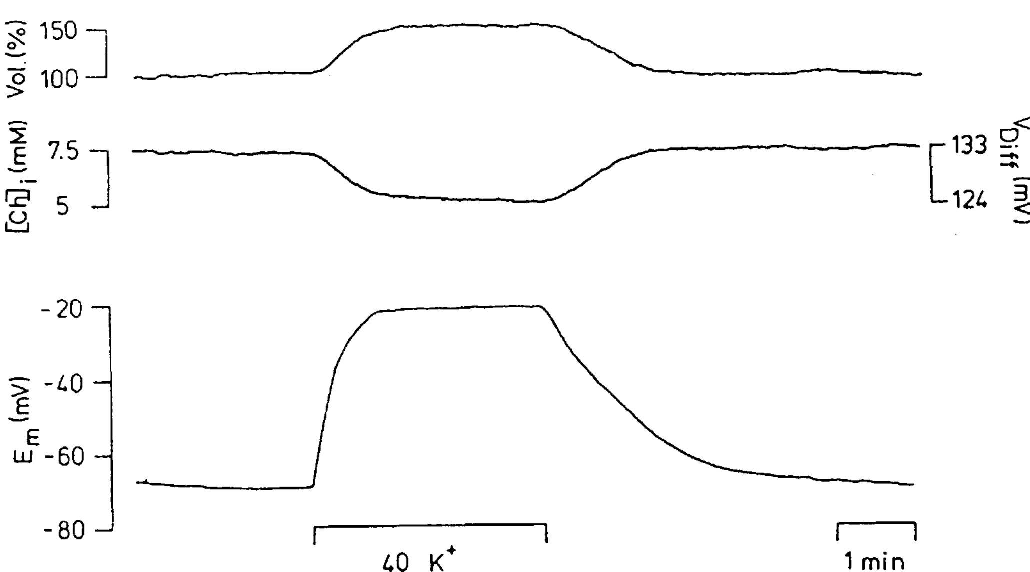

FIG. 18-4. Relationship between a K^+-induced change in the intracellular free choline (Ch) concentration ($[Ch]_i$), relative cell volume (Vol.) and membrane potential (E_m) in a leech neuropile glial cell. The cell was loaded with Ch via bath application (5 mM, 1 minute) about 5 minutes prior to the recording. Elevation of the extracellular K^+ concentration from 4 to 40 mM led to a prominent depolarization and a concomitant decrease of $[Ch]_i$. This reversible decrease corresponds to a cell swelling of 50% (for details, see Ballanyi and Grafe, 1988). The volume trace is identical with the $[Ch]_i$ trace (opposite polarity). V_{Diff} is the difference signal of the double-barreled ion-sensitive microelectrode, filled with the Corning K^+-exchanger. [From Ballanyi et al. (1990), with permission.]

K^+-Independent Modulation of aK_i, aNa_i, and aCl_i

In addition to the effects of changes in extracellular K^+, glial depolarizations or hyperpolarizations can be elicited by the direct action of neurotransmitters, extracellular ions like HCO_3^- or by drugs, affecting glial membrane conductances and/or ion transporters (see Chapters 14 and 21). During Ba^{2+}-induced depolarizations, aK_i and aCl_i can increase by more than 10 mM with a concomitant and sustained decrease of aNa_i (Figure 18-6) (see also Ballanyi et al., 1987). The increase of aK_i results from a Ba^{2+}-evoked blockade of K^+ channels (see above), which leads to a reduction of outward leakage of K^+. Ongoing Na^+/K^+ pump activity then produces accumulation of intracellular K^+. The fall in aNa_i can be explained by a reduced driving force for inward leakage of Na^+ in combination with Na^+ extrusion via the Na^+/K^+ pump. The increase of aCl_i is due to a passive redistribution of Cl^-.

Depolarizations of mouse oligodendrocytes, evoked by intracellular injection of Na^+ or Li^+, lead to profound decreases of aK_i as a result of an increased driving force for K^+ outward movements via K^+ channels (Kettenmann et al., 1987). A similar decrease of aK_i by up to 30 mM, and corresponding increases of aNa_i and aCl_i were revealed during glial depolarizations, evoked by activation of glial non-NMDA glutamate (Ballanyi and Kettenmann, 1990; Dörner et al., 1990) or nicotinic acetylcholine receptors (Ballanyi and Schlue, 1989), which are presumably coupled to nonspecific cation conductances (see Chapter 21, this volume). In a major population of cultured mouse oligodendrocytes, GABA activates Cl^- channels, which leads to a depolarization and to a concomitant decrease of aCl_i (Hoppe and Kettenmann, 1989b).

Glial hyperpolarizations can, for example, be elicited by serotonin (Schlue and Walz, 1984). The serotonin-induced hyperpolarization is accompanied by a passive fall of aCl_i (Ballanyi and Schlue, 1990) and a glial shrinkage of more than 10% (Ballanyi et al., 1990), whereas aK_i and aNa_i remain almost unaffected (Figure 18-7) (see also Brune et al., 1992).

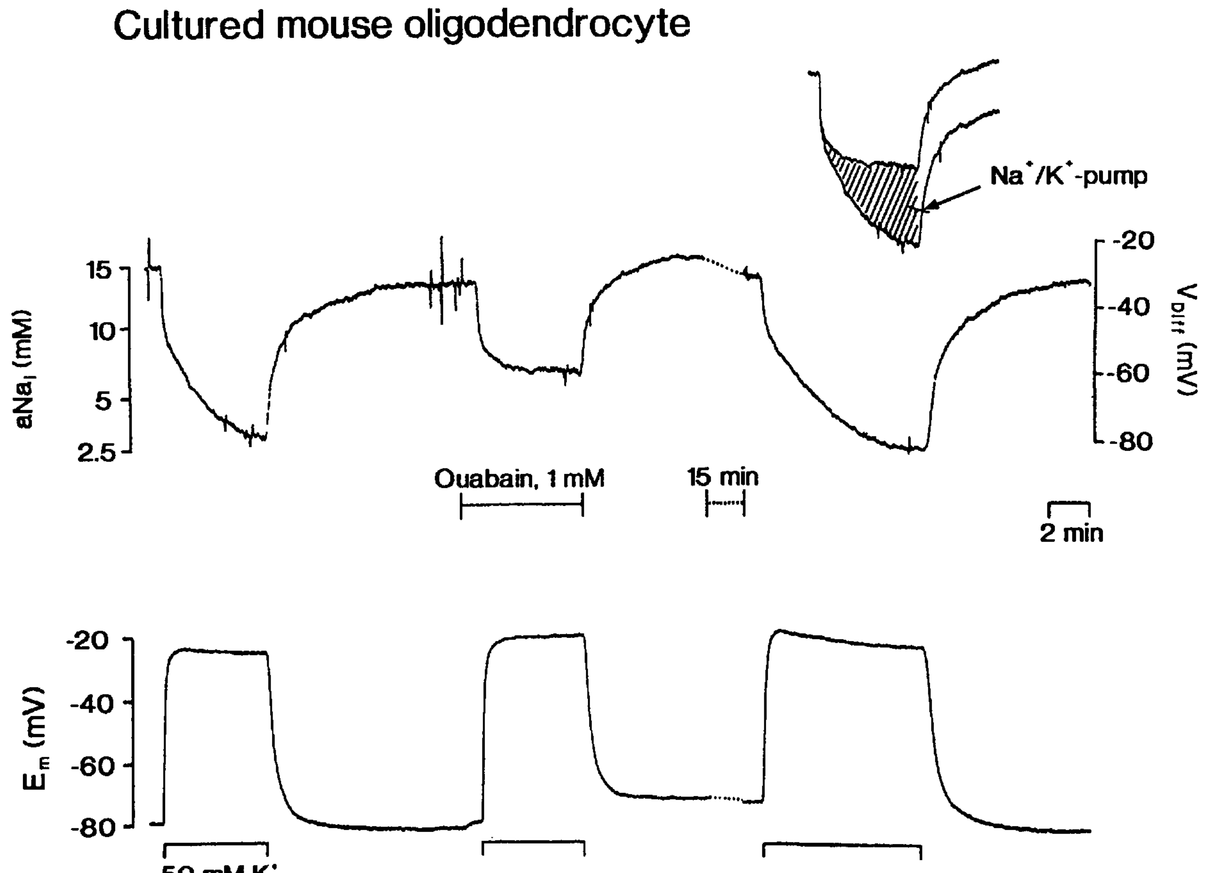

FIG. 18-5. Ouabain blocks the slow component of the K^+-induced decrease of intracellular Na^+ activity (aNa_i) in a cultured mouse oligodendrocyte. In this cell, ouabain had only a small effect on resting aNa_i and membrane potential (E_m). The *inset* shows superimposed traces of the aNa_i decrease in the control situation and in the presence of ouabain. The marked area indicates the contribution of the Na^+/K^+ pump to the K^+-induced fall of aNa_i. [From Ballanyi and Kettenmann (1990), with permission.]

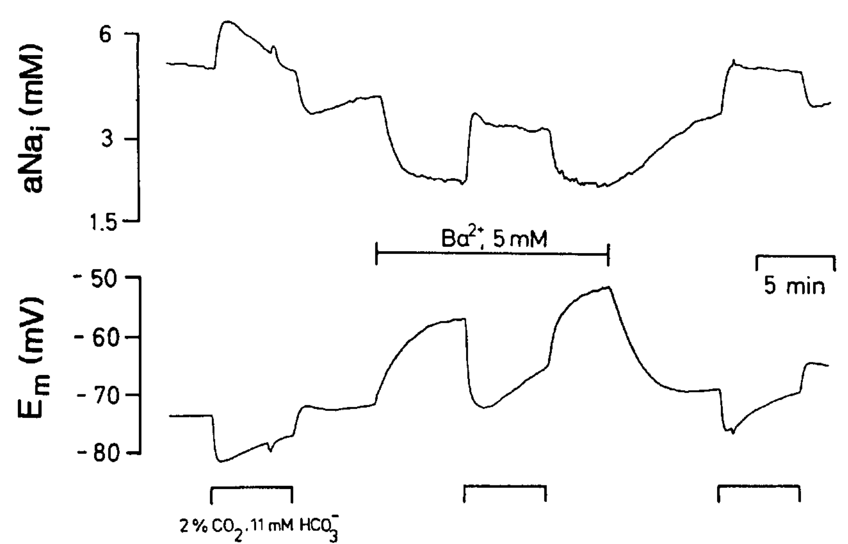

FIG. 18-6. Changing the superfusion medium from a CO_2/HCO_3^--free, HEPES-buffered solution to a saline, buffered with 2% CO_2/11 mM HCO_3^-, produced a hyperpolarization and an increase of intracellular Na^+ activity (aNa_i) in a leech neuropile glial cell. Both these effects are due to activation of an inwardly directed, electrogenic Na^+-HCO_3^- cotransport (see Deitmer and Schlue, 1989). Subsequent to the recovery, addition of Ba^{2+} produced a depolarization of membrane potential (E_m) by blockade of K^+ channels. The concomitant decrease of aNa_i can be explained by a reduced inward leakage of Na^+. In the presence of Ba^{2+}, both the CO_2/HCO_3^--induced hyperpolarization and aNa_i increase are potentiated in amplitude. [K. Ballanyi, unpublished observations.]

The hyperpolarization is due to activation of a serotonin receptor-coupled K^+ conductance, leading to a K^+ efflux. This K^+ efflux is paralleled by an equimolar efflux of Cl^- and of water which explains the shrinkage of the cells. aK_i does not change, since the loss of K^+, relative to the total content of dissolved cell K^+, is similar to the percentage change of cell volume (see above). aCl_i decreases despite the concentrating effect of the cell shrinkage, as it is much lower than aK_i (for details, see Orkand et al., 1986; Ballanyi and Grafe, 1988).

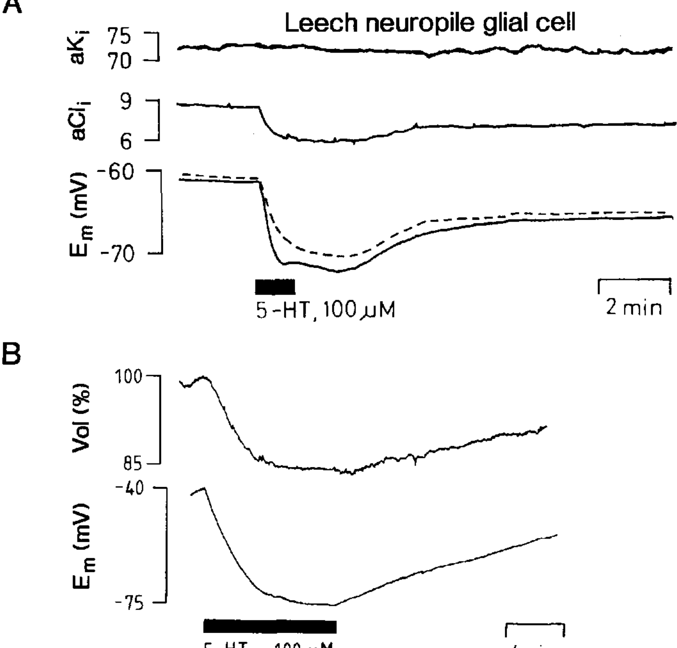
A similar passive decrease of aCl_i can be observed during hyperpolarizations of leech neuropile glial cells, elicited by changing the superfusion medium of the ganglia from salines which are nominally CO_2/HCO_3^--free to solutions containing CO_2/HCO_3^- (Ballanyi and Schlue, 1990). However, in contrast to the serotonin-induced hyperpolarizations, CO_2/HCO_3^--dependent hyperpolarizations lead to an increase of aNa_i and aK_i in these cells (Deitmer and Schlue, 1989; Brune et al., 1992) (Figure 18-6). The CO_2/HCO_3^--related hyperpolarization and aNa_i increase can be explained by activation of an inwardly directed, electrogenic Na^+-HCO_3^- cotransport (Deitmer and Schlue, 1989; Chapter 14, this volume), whereas the mechanism of the concomitant increase of aK_i remains to be analyzed (Brune et al., 1992).

Finally, it should be mentioned that glial ion activities can be modulated without an apparent change of glial E_m. In pigment epithelial glia of the drone retina, long-term illumination at physiological intensities evokes a maintained increase of aK_i subsequent to the recovery of aK_e and E_m from their initial and transient light-evoked perturbances (Coles and Schneider-Picard, 1989). The authors speculated that some unidentified physiological transmitters might have electrically silent effects on the glia (see also Chapter 52).

CONCLUSIONS

In glial cells of different central nervous system preparations, the activities of K^+, Na^+, and Cl^- (aK_i, aNa_i, aCl_i) undergo rather substantial changes during changes of the extracellular milieu (Figure 18-8). K^+, released by the neurons, elicits significant increases of glial aK_i and aCl_i as well as decreases of aNa_i, confirming the relevance of glial K^+ buffering for ion homeostasis of the brain. Neurotransmitters, as well as metabolites, that are also released into the extracellular space during physiological or pathophysiological processes in the brain, can directly evoke sustained changes of glial aK_i, aNa_i, and aCl_i independently and, in several cases, opposite to those during elevation of extracellular K^+.

I would like to thank Drs. D. W. Richter, G. Burckhardt, and S. W. Schwarzacher for a critical reading of the manuscript.



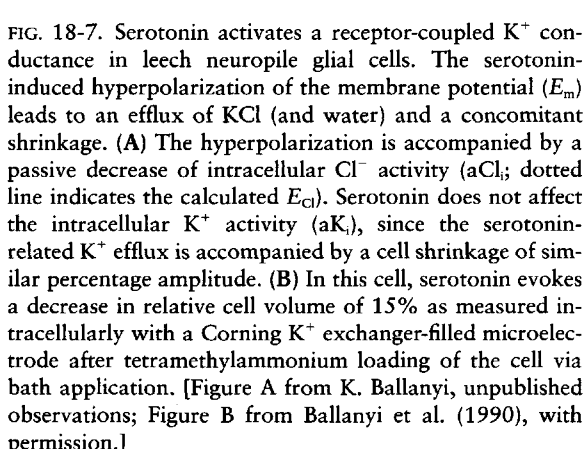


FIG. 18-7. Serotonin activates a receptor-coupled K^+ conductance in leech neuropile glial cells. The serotonin-induced hyperpolarization of the membrane potential (E_m) leads to an efflux of KCl (and water) and a concomitant shrinkage. (**A**) The hyperpolarization is accompanied by a passive decrease of intracellular Cl^- activity (aCl_i; dotted line indicates the calculated E_{Cl}). Serotonin does not affect the intracellular K^+ activity (aK_i), since the serotonin-related K^+ efflux is accompanied by a cell shrinkage of similar percentage amplitude. (**B**) In this cell, serotonin evokes a decrease in relative cell volume of 15% as measured intracellularly with a Corning K^+ exchanger-filled microelectrode after tetramethylammonium loading of the cell via bath application. [Figure A from K. Ballanyi, unpublished observations; Figure B from Ballanyi et al. (1990), with permission.]

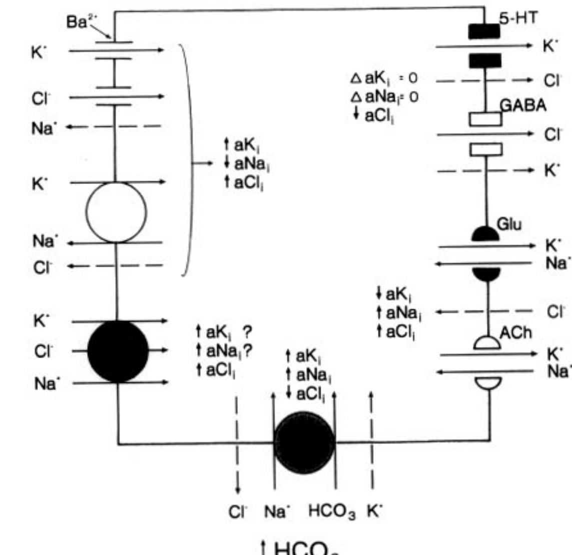

FIG. 18-8. The scheme summarizes the effects of elevated concentrations of extracellular potassium (K^+) and bicarbonate (HCO_3^-) as well as of the neurotransmitters serotonin (5-HT), γ-aminobutyric acid (GABA), glutamate (Glu) and acetylcholine (ACh) on glial activities of K^+, Na^+, and Cl^- (aK_i, aNa_i, aCl_i). Both 5-HT and GABA produce an equimolar efflux of KCl, which leads to a decrease of aCl_i, but not of aK_i ($\Delta aK_i = 0$) or aNa_i ($\Delta aNa_i = 0$) due to the concomitant cell shrinkage (see text). Both Glu and ACh, activate a nonspecific cation conductance, which results in an increase of aNa_i and a decrease of aK_i. The increase of aCl_i during the action of Glu and ACh can be explained by a passive redistribution of Cl^-. Secondary, passive ion movements are indicated by dotted lines. The left side of the scheme summarizes mechanisms, contributing to glial ion accumulation in response to elevated K^+. **Top**: Channel-mediated, passive KCl uptake by a Donnan-like redistribution, which is inhibited by the K^+ channel blocker Ba^{2+}. **Center** (*open circle*): K^+ uptake via the electrogenic Na^+-K^+ pump, which is blocked by ouabain. During profound neuronal activity, both these transport systems are active. **Bottom** (*filled circle*): Na^+-K^+-$2Cl^-$ cotransport, which is inhibited by furosemide, appears to be involved in maintenance of an aCl_i above equilibrium in some glial cells. Activation of electrogenic Na^+-HCO_3^- cotransport (*shaded circle*), which can be blocked by DIDS, can have long-term effects on aK_i, aNa_i, and aCl_i. Most of these ion movements are accompanied by water movements. (For details see text.)

19 Gap junctions

BRUCE R. RANSOM

An intriguing form of intercellular communication is mediated by large channels called gap junctions that directly link the cytoplasmic interiors of cells (Loewenstein, 1981). Nearly every type of mammalian cell exhibits a degree of this form of interaction except mature skeletal muscle, spermatozoa, and erythrocytes (Dermietzel and Spray, 1993). Cellular coupling mediated by gap junctions is common in the nervous system, primarily among glial cells (Kuffler and Nicholls, 1967; Dermietzel and Spray, 1993). The characteristics and possible functions of these channels in glial cells are the focus of this review. As a necessary preliminary to discussing glial coupling, however, the general properties of gap junctional communication are surveyed.

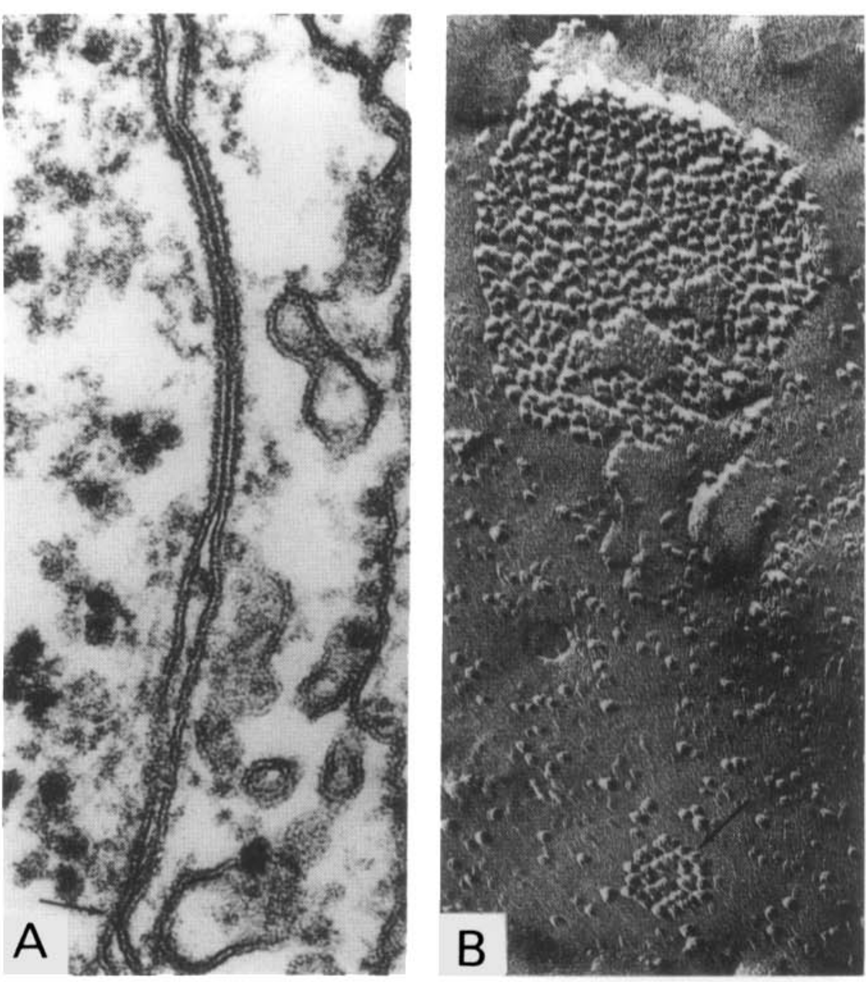
Direct intercellular coupling was first demonstrated in 1952 by Weidmann who showed that voltage changes in individual heart muscle cells were conveyed to neighboring cells (Weidmann, 1952). Electrical communication between neurons was demonstrated a few years later in the crayfish, representing the first example of an electrical synapse (Furshpan and Potter, 1959). Similar electrical communication was seen by Kuffler and his colleagues between glial cells in the leech central nervous system (Kuffler and Potter, 1964). How such electrical interactions might occur was not initially clear. The discovery by Kanno and Loewenstein (1964) that large molecules could pass between electrically coupled cells suggested the notion of a specific channel linking the cells. Shortly thereafter, the concept emerged that proteins formed membrane channels, and it was soon recognized that specialized membrane contacts mediated direct intercellular communication (Loewenstein, 1981); these contacts became known as gap junctions, based on electromicroscopic studies showing that at these sites adjacent membranes are more closely opposed, narrowing the extracellular space to a small "gap" (Revel and Karnowsky, 1967).

The channels comprising a gap junction are large-diameter aqueous pores that extend from one cell, across the extracellular space, into an adjacent cell. These channels allow all inorganic ions and small organic molecules to diffuse freely from the interior of one cell into the interior of another cell. The discovery of gap-junctional communication challenged the fundamental concept of classical cell theory, which states that individual cells are autonomous functional units. When cells are connected with their neighboring cells by gap junctions, the functional unit is no longer the individual cell of classical cell theory but rather the large aggregate of cells that are so joined, because they share so much of their cytoplasmic contents (Loewenstein, 1981). The strength of coupling between cells that form gap junctions with each other is highly variable, however, and the above statement is relevant primarily to strongly coupled cells.

GENERAL FEATURES OF GAP JUNCTIONS

Structure and Molecular Biology

In electron micrographs, gap junctions appear as discrete areas where the cell membranes of adjacent cells closely approach one another, leaving a narrow gap of only about 2 nm (Figures 19-1A and 19-2). These junctions have a seven-layer (septilaminar) appearance because a small layer of extracellular space can be seen between the three-layered cell membranes (Brightman and Reese, 1969) (Figure 19-2B). Using the freeze-fracture technique, a cluster of homogeneous intramembrane particles can be demonstrated on the cytoplasmic fracture face of the plasma membranes involved in the gap junction (Figure 19-1B). Each of these particles represents a gap junction hemichannel, and has been termed a *connexon* (Caspar et al., 1977). The diameter of the central hole in each connexon appears to be about 2 nm, with slight narrowing of the opening on the extracellular side of the membrane (Makowski, 1985) (Figure 19-1C). X-ray diffraction experiments indicate that each connexon hemichannel is composed of six symmetrical subunits (Makowski et al., 1977), but other investigators have observed that connexon particles are frequently composed of only 4 or 5 subunits (Hanna et al., 1985). Nevertheless, the most widely accepted model of a connexon



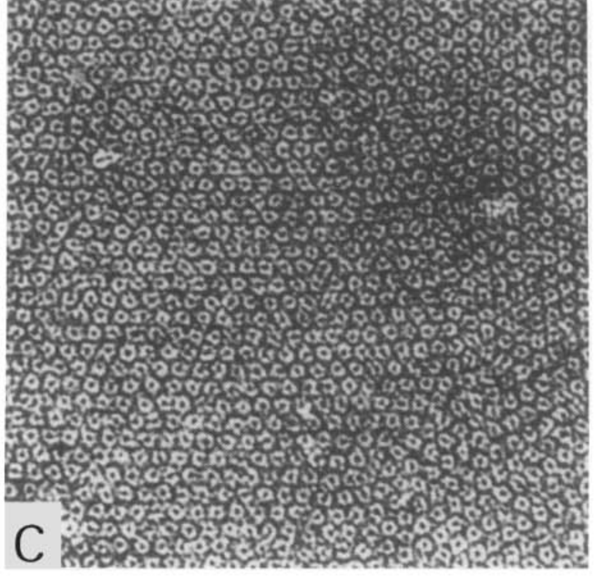


FIG. 19-1. Ultrastructural features of gap junctions between fibroblasts (A, B) and liver cells (C). (**A**) Transmission electron microscopy shows the characteristic close membrane apposition at sites where cells form gap junctions. A large junction and a small junction (*arrow*) are shown. Bar = ~200 μm. (**B**) Freeze fracture technique shows aggregates of membrane particles at gap junctions. Again, a large and a small (*arrow*) gap junction are shown. (**C**) Electron micrograph showing part of an isolated gap junction from rat liver. This oblique or *en face* view illustrates the tightly packed organization of the connexons which make up gap junctions. Each connexon has a densely stained center hole with a diameter of about 2 nm, which is presumed to be an aqueous pore. [Figures A and B from Gilula (1974) and Figure C from Gilula (1978), with permission.]

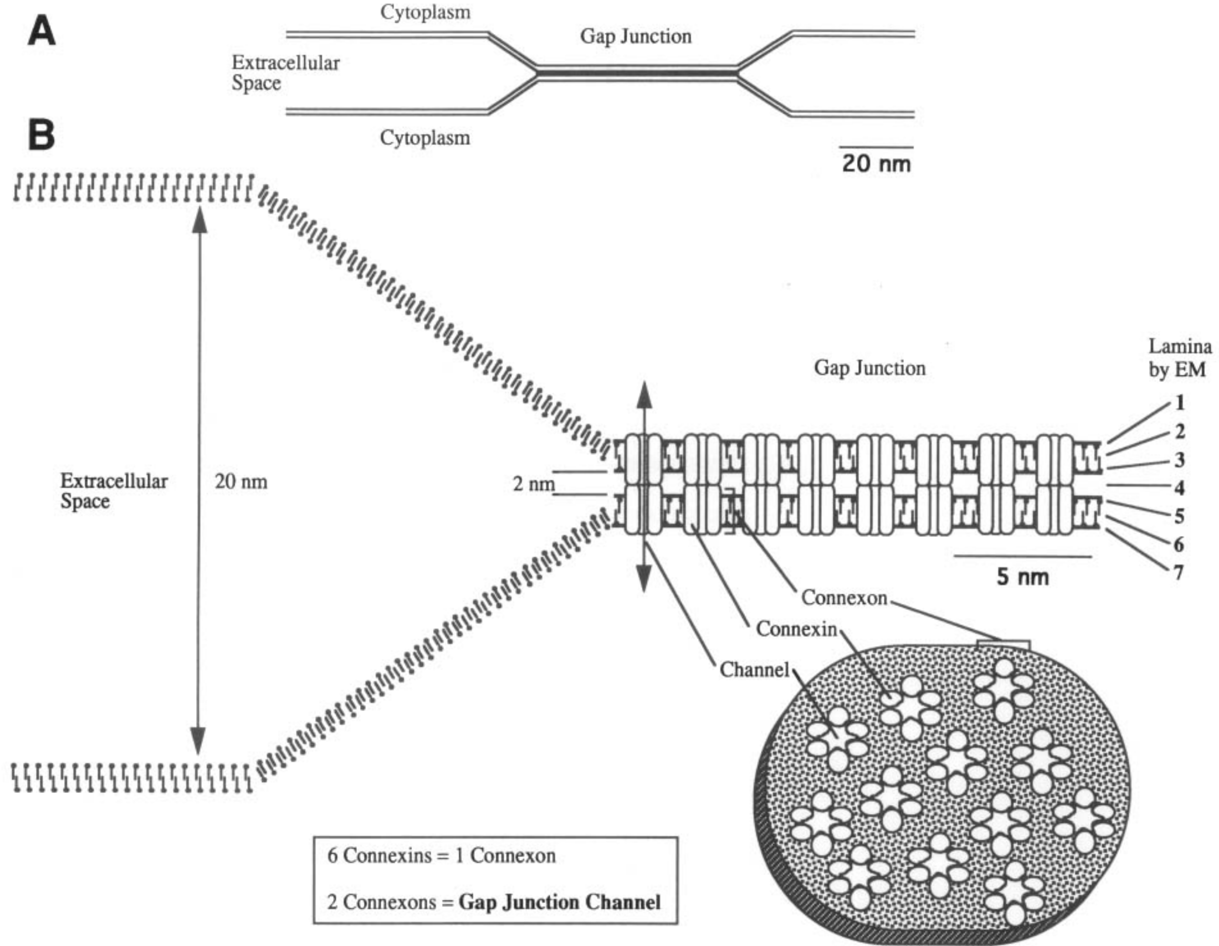

FIG. 19-2. Idealized diagram of a gap junction based on x-ray diffraction and electron microscope studies. (**A**) Low-power electron-microscopic appearance of a gap junction. The junction looks five-layered at this magnification. (**B**) At higher magnification, the small slit of extracellular space that remains between cells at the junction is easily seen and the structure looks seven-layered (septilaminar). The gap junction is believed to be composed of six identical connexin proteins which form hemichannels called connexons (Makowski et al., 1977). Two connexons connect with one another and bridge the extracellular space. The insert figure shows a section of gap junction in *en face* perspective, that is, as if the gap junction were separated in the middle and viewed from the extracellular side.

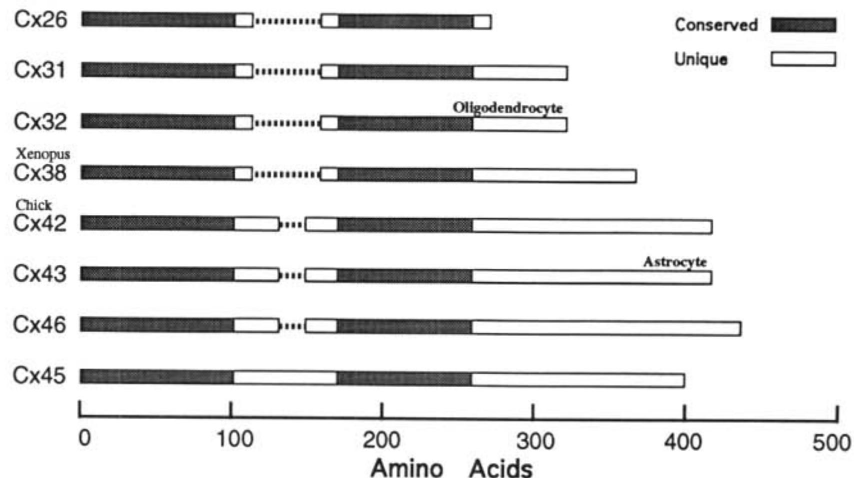
hemichannel is the aggregation of six identical protein molecules, called *connexins* (Goodenough, 1974) (Figure 19-2B). A gap junction channel is formed when a connexon in one cell comes into perfect alignment with a second connexon in an adjacent cell; exactly how this occurs is not understood (Bennett et al., 1991). Structural studies indicate that hundreds of functional gap channels may aggregate at a given gap junction.

Significant progress has been made in the isolation and characterization of the proteins that form gap junctions (Dermietzel et al., 1990; Bennett et al., 1991; Beyer, 1993). About a dozen putative connexin proteins have been identified in mammalian tissues and seem to arise from two distinct gene families (Haefliger et al., 1992). The two major subclasses of these proteins, based on similar gene structure and about 50% amino acid sequence homology, are typified by connexins derived from liver and heart (Figure 19-3A). The gap junction proteins derived from liver have molecular weights of 26 kD and 32 kD (i.e., connexin26 and connexin32) and the gap junction protein derived from heart has a molecular weight of 43 (connexin43) (Bennett, et al., 1991). These connexin proteins are distributed in a nonrandom way in mammalian tissues, including the brain (Dermietzel and Spray, 1993). The cellular pattern of connexin expression within the brain is becoming clear; neurons and oligodendrocytes express connexin32, astrocytes express connexin43, and ependyma and leptomeningeal cells express both connexin26 and connexin43. Connexin43, however, is more strongly expressed than any of the others (Dermietzel et al., 1989), which is consistent with



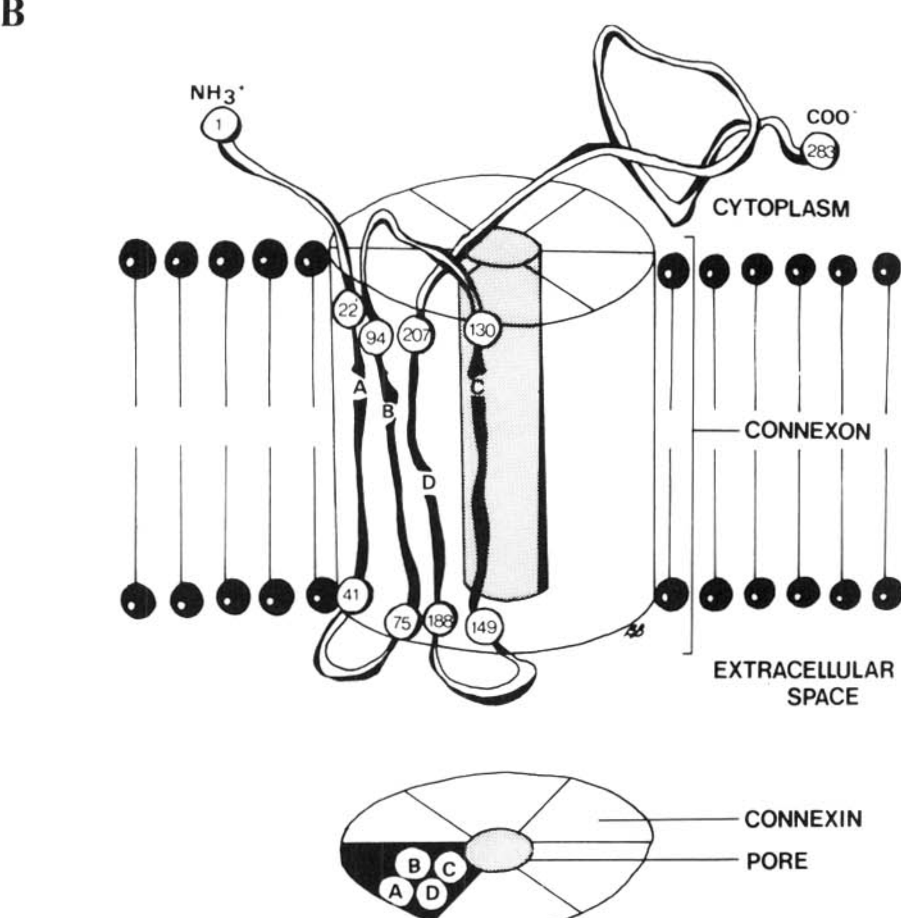


FIG. 19-3. Connexin proteins make up junctions. (**A**) The amino acid sequences of several cloned connexins are compared in this diagram. Regions where the amino acid sequences are highly similar are *shaded*. *Dashes* represent spaces added to optimize alignment. Evidence suggests that connexin32 and connexin43 make up gap junctions in oligodendrocytes and astrocytes, respectively. [Adapted from Beyer (1993), with permission.] (**B**) Diagram illustrating the manner in which an individual connexin is inserted into the membrane. There are four membrane spanning regions and the N terminus and C terminus are both located on the cytoplasmic side of the membrane. Six similar molecules are presumed to make up each connexon. [From Dermietzel et al. (1991), with permission.]

the fact that astrocytes show the strongest functional coupling (Kettenmann and Ransom, 1988; see "Astrocytes" below).

That connexins actually mediate functional intercellular communication is attested to by the following observations: (1) connexin mRNA can induce cell-cell channel formation (Dahl et al., 1987); (2) connexin protein reconstituted into artificial membranes produces channels that have the expected biophysical behavior (Spray et al., 1986); and (3) intracellular injection of antibodies against connexin blocks cell coupling (Hertzberg et al., 1985; Dudek et al., 1988). Moreover, strong evidence supports the corollary expectation that connexins form gap junctions. For example, poorly coupled glioma cells that do not express gap junctions can be induced, by transfection with connexin43 cDNA, to express both gap junctions and coupling; the gap junctions are specifically marked by antibodies to connexin43 (Naus et al., 1993).

The manner in which connexins are inserted into membranes has been deduced on the basis of hydropathicity plots and via the use of site-specific antibodies and proteolytic degradation (Hertzberg et al., 1988; Dermietzel et al., 1990), and a plausible model is shown in Figure 19-3B. Because there are four hydrophobic amino acid sequence domains, it is presumed that the protein crosses the membrane four times. Both the N terminus and the C terminus of connexin proteins are believed to lay on the cytoplasmic side of the membrane, resulting in two extracellular and one intracellular loop. The greatest degree of homology between connexin proteins occurs in the membrane spanning regions and in the two extracellular loops, while substantial variability is noted in the length and amino acid composition of the cytoplasmic sections, especially the C terminus (Bennett et al., 1991). The protein segments that form the walls of the aqueous channel may be more hydrophilic than the other membrane-spanning regions and, perhaps, have a slight excess of negative charges explaining the tendency toward reduced permeation by large negatively charged molecules (Neyton and Trautwein, 1985).

It is well established that nonsimilar cells, that is, from different organs or different species, may form gap junctions with one another (Loewenstein, 1981; Bennett et al., 1991). This observation suggested, and subsequent experiments have proven, that connexon hemichannels of different protein composition may form functional gap junction channels with one another. Details about the biophysical function of these heterologous channels are still forthcoming, but such channels may have unique permeability characteristics (Robinson et al., 1993; see "Oligodendrites" below).

Biophysical Properties

The minimal diameter of the gap junction channel in vertebrates is about 1.6 nm (Schwarzmann et al., 1981). These pores are permeable to molecules up to a molecular weight of approximately 1 kD, largely independent of charge (Loewenstein, 1981). As a consequence, coupled cells are able to exchange a wide range of biologically important molecules, including cyclic nucleotides, small molecules of intermediary metabolism, vitamins, and inorganic ions (Saez et al., 1989). This does not necessarily imply that coupled cells will have identical concentrations of all permeant molecules; the concentration of a given permeant molecule in each cell would depend on the transmembrane fluxes, and production and removal of the molecule in question, in addition to the gap junctional permeability of that molecule (Neyton and Trautwein, 1985; Bennett et al., 1991). Obviously, the tendency for coupled cells to have the same concentration of a cytoplasmic constituent will increase with the strength of coupling.

Electrophysiological analysis of single gap junction channels indicate that they abruptly open and close in a manner similar to that of other ion channels (Neyton and Trautwein, 1985; Bennett et al., 1991). The conductance of individual gap junction channels has been measured and appears to vary with the type of connexin protein from which the channel is constructed. The unitary conductance for connexin32 channels is about 120 to 150 pS, and for connexin43 channels this value is about 50 pS (Bennett et al., 1991). Questions remain about the possible existence of subconductance states, the extent to which single-channel conductance might be modified by membrane environment, and the biophysical characteristics of channels composed of other connexin proteins. Given the fact that gap junction channels are permeable to much larger molecules than conventional ion channels, it is surprising that the unitary conductance of gap junction channels is actually smaller than some ion channels such as the "big K" (BK) Ca^{2+}-activated K^+ channel (i.e., 200 to 300 pS) (Blatz and Magelby, 1987). One explanation may be the simple fact that the gap junction channel is physically longer than an average ion channel because it spans two membrane bilayers instead of one (Bennett et al., 1991); this would increase the channel's total electrical resistance, that is, decrease its conductance.

The permeability of gap junction channels is influ-

enced by a number of physiological variables, primarily transjunctional voltage, and the intracellular concentrations of H^+ and Ca^{2+}. The exact mechanisms by which these factors "gate" conductance are not known, but Unwin (1989) has proposed an operational model based on electron-microscopic studies. Under conditions where the channel would be expected to be closed, the protein subunits of the channel appear tilted. It is hypothesized that in the tilted state the alignment of the protein segments forming the walls of the channel pore is altered in such a manner that some of their constituent amino acids move into a channel-blocking position.

The voltage sensitivity of gap-junctional conductance depends on the type of connexin protein that forms the junction. Junctions formed by connexin32, the connexin primarily expressed by oligodendrocytes (Dermietzel et al., 1989), are closed by transjunctional voltage gradients of either sign, but the degree of sensitivity is low (Bennett et al., 1991). The connexin protein making up astrocytic gap junctions, connexin43, is less voltage-sensitive (Dermietzel et al., 1991). Increases in intracellular concentrations of either H^+ or Ca^{2+} rapidly decrease junctional conductance (Loewenstein, 1981; Spray et al., 1981). Coupling conductance is sensitive to changes in intracellular pH that are within the physiological range of this variable (i.e., 6.5 ± 0.5 pH; Bennett et al., 1988). The increases in intracellular Ca^{2+} that result in decreased junctional conductance are high (e.g., ≥10 μM) and this variable is not likely to affect coupling under normal physiological conditions (DeMello, 1982; but see Lazrak and Peracchia, 1993); cell injury causes large increases in intracellular [Ca^{2+}], which could lead to uncoupling. Lipophilic agents such as the higher order alcohols heptanol and octanol, and the anesthetic halothane, block gap junction channels (Spray and Bennett, 1985) but the mechanism of blockade by these agents is not known. The sensitivity of junctional conductance to octanol varies considerably among astrocytes from different brain regions (Lee et al., 1994), even though they would be expected to express the same connexin protein.

Second messengers have complex effects on gap-junctional conductance (Bennett et al., 1991). For example, elevation of cyclic adenosine monophosphate (cAMP) increases junctional conductance in hepatocytes and myocytes, expressing connexin32 and -43, respectively, while decreasing the gap junction conductance of uterine muscle cells, also expressing connexin43. These changes occur within minutes, suggesting phosphorylation or effects on channel gating. In other systems, an increase of cAMP increases junctional conductance over a period of hours; this effect can be prevented by blocking mRNA or protein synthesis, suggesting that channels are being newly synthesized. It is worth noting that the turnover of connexin proteins appears to be rapid, with protein lifetimes of several hours (Bennett et al., 1991). These second-messenger effects, which may be initiated by a wide range of agents, including hormones and neurotransmitters, imply an important degree of plasticity in the control of physiological events mediated by gap-junctional communication. Several excellent reviews may be consulted for more detailed general information about the molecular biology and biophysics of gap junctions (Loewenstein, 1981; Bennett et al., 1991; Dermietzel et al., 1991; Beyer, 1993).

GAP JUNCTIONS IN GLIAL CELLS

Distribution and Anatomy

Gap junctions are found in most mammalian glial cells (Brightman and Reese, 1969; Mugnaini, 1986; Peters et al., 1991). Only microglial cells seem devoid of these junctions. Mammalian Müller cells, specialized glia of the retina (Chapter 4, this volume), do not exhibit gap junctions except *in vitro* (Uga and Smelser, 1973; Wolburg et al., 1990); nonmammalian Müller cells, however, express them (Mobbs et al., 1988). The electron-microscopic and freeze-fracture features of glial gap junctions are similar to what has been described in other cells (Mugnaini, 1986; Peters et al., 1991) (see Figure 19-1). The ultrastructural demonstration of gap junctions between cells is well correlated with the presence of functional intercellular communication between them (Loewenstein, 1981), but ultrastructural analysis alone can not define the strength or pattern of physiological cell coupling.

Astrocytes of various types (i.e., protoplasmic, fibrous, Bergmann cells) form numerous gap junctions with other astrocytes (Brightman and Reese, 1969; Dermietzel, 1974; Massa and Mugnaini, 1982; Mugnaini, 1986), and with oligodendrocytes (Massa and Mugnaini, 1985; Mugnaini, 1986) and ependymal cells (Mugnaini, 1986). The extent to which gap junctions form between fibrous (primarily in white matter) and protoplasmic astrocytes (primarily in gray matter) is unclear (Mugnaini, 1986). Type-2 astrocytes of the rat optic nerve (following the nomenclature of Raff, 1989) do not show coupling *in vitro* (Sontheimer et al., 1990), suggesting the possibility that not all astrocytes are coupled to one another (see below). Gap junctions are expressed by

astrocytes making up human brain tumors (i.e., astrocytomas), but are markedly decreased in the most malignant type of astrocyte tumor, glioblastoma multiforme (Tani et al., 1973). Considerable evidence suggests that the loss of gap-junctional communication may be associated with neoplasia (Loewenstein, 1981; Klaunig and Ruch, 1990).

Few, if any, gap junctions are found between oligodendrocytes in white matter of the cat, although gap junctions are abundant between oligodendrocytes and astrocytes (Massa and Mugnaini, 1982; Mugnaini, 1986). It was proposed that communication between oligodendrocytes is only possible via their connections with the astrocytic syncytium (Massa and Mugnaini, 1985). The generality of this scheme, however, is questioned by the demonstration of gap junctions between purified oligodendrocytes from rat (Gonatas et al., 1982) and cow (Wollman et al., 1981), and the finding of functional coupling between oligodendrocytes (i.e., without communication through astrocytes) *in vitro* (Kettenmann and Ransom, 1988; Blankenfeld et al., 1993; Ransom and Kettenmann, 1990) and *in situ* (Berger et al., 1991; Butt and Ransom, 1993; Robinson et al., 1993).

Nonmyelinating Schwann cells *in vitro* exhibit dye coupling, which disappears when they begin to make myelin (Konishi, 1990); gap junctions between these cells have not been reported, but this may simply be for want of a properly timed ultrastructural study. Enteric glia express gap junctions (Gabella, 1981) and robust intercellular coupling (Hanani et al., 1989). Ependymal cells form gap junctions with each other and with astrocytes (Brightman and Reese, 1969; Mugnaini, 1986). The specialized glial cells of the intermediate lobe of the pituitary, called *stellate glia,* exhibit gap junctions and functional coupling (Mudrick-Donnon et al., 1993).

Dye and Electrical Coupling

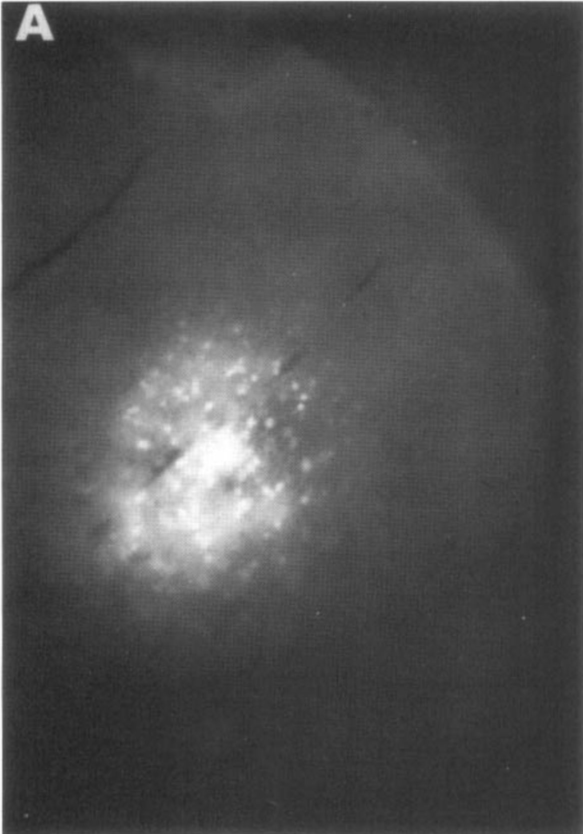
The possibility that mammalian glial cells might be coupled to one another was suggested by indirect electrophysiological observations; the closed field distribution of glial-generated cortical slow potentials resulting from electrical stimulation (Ransom, 1974; Somjen, 1970), the low input resistance of cortical glia (Trachtenberg and Pollen, 1970), and the depolarization of glial cells in sites within the cortex that are distant from focal accumulations of K^+ (Futamachi and Pedley, 1976), all imply that mammalian glia form an electrical syncytium. Subsequently, coupling between glial cells has been studied in three ways:

1. A junction-permeable fluorescent dye such as lucifer yellow is injected into individual cells to see if it diffuses into adjacent cells (Ransom and Sontheimer, 1992). This technique provides primarily qualitative information.
2. Microelectrodes are placed in two nearby cells to determine if current injected into one cell passes into the other cell (e.g., Kettenmann and Ransom, 1988). The strength of coupling can be quantified by measuring the voltage or current that is transferred between the two cells.
3. The newest method for measuring coupling uses laser light to bleach and destroy the fluorescent dye molecules in an individual cell; strength of coupling to adjacent cells is judged by the speed with which dye diffuses back into this cell from nearby cells via gap junctions (Sontheimer, 1992). This method is termed laser photobleaching.

Nonmammalian Glial Cells. Direct electrical communication between nonmammalian glial cells, was firmly established by Kuffler and his colleagues in studies on the leech central nervous system (Kuffler and Potter, 1964) and the mudpuppy optic nerve (Kuffler et al., 1966; Cohen, 1970). Conventional gap junctions appear to mediate coupling between glial cells in the leech (Coggeshall, 1974). The possibility of coupling between neurons and glial cells was directly tested in the leech, and these two cell types were not coupled (Kuffler and Potter, 1964). Glial cells in the mudpuppy optic nerve show strong dye-coupling and this is blocked by cytoplasmic acidification (Tang et al., 1985).

In fish, in contrast to invertebrates, macroglial cells are divisible into astrocytes and oligodendrocytes (Diaz-Regueira et al., 1992). Gap junctions are seen between the somata of oligodendrocytes and between the processes of astrocytes (Diaz-Regueira et al., 1992), and fish astrocytes are dye-coupled *in vitro* (Hoppe et al., 1991).

Astrocytes. Mammalian astrocytes usually, but not always, show widespread dye-coupling with each other. When lucifer yellow is injected into individual cortical astrocytes as many as 100 adjacent cells are stained (Figure 19-4) (Gutnick et al., 1981; Connors et al., 1984; Binmöller and Müller, 1992). The coupled cells form spherical arrays, suggesting that lucifer yellow diffuses from the injected astrocyte into uniformly coupled surrounding cells. All of the cells in the coupled arrays have a similar appearance, but only the injected cell could be clearly evaluated as to cellular detail (Figure 19-4B); these cells have the appearance of protoplasmic astrocytes (Gutnick et al., 1981). White matter astrocytes are also highly



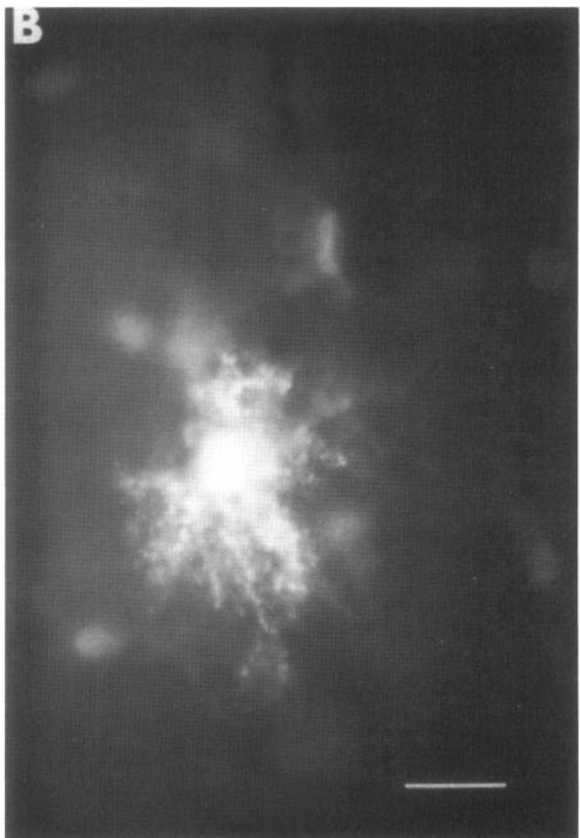


FIG. 19-4. Fluorescent dye coupling between astrocytes in guinea pig neocortical brain slice. (**A, B**) Photomicrographs of the same field at different magnifications. A single cell, identified by physiological criteria as a glial cell, was injected with lucifer yellow (*LY*). The central, brightly stained cell, has characteristics of a protoplasmic astrocyte (*B*), and is surrounded by numerous, less intensely stained cells with similar features (*A* & *B*). Scale: 200 μm in Figure A, 50 μm in Figure B. [Adapted from Gutnick et al. (1981), with permission.]

dye-coupled *in situ* (Figure 19-5A–C) (Butt and Ransom, 1989; Butt and Ransom, 1993). *In vitro* studies of white matter astrocytes, derived from optic nerve, indicate that dye-coupling is restricted to type-1 astrocytes, with type-2 astrocytes devoid of coupling to each other or to the type-1 cells (Sontheimer et al., 1990); consistent with this observation, only the type-1 cells express connexin43 (Belliveau and Naus, 1994). Presently, however, the existence of a unique astrocyte in the mammalian central nervous system with characteristics similar to the type-2 astrocyte defined *in vitro*, is controversial (Fulton et al., 1991). Moreover, studies of astrocyte dye-coupling *in situ* have thus far failed to detect subpopulations of non-coupled astrocytes (Butt and Ransom, 1993). Surprisingly, cat neocortical astrocytes studied *in vivo* did not exhibit dye-coupling (Takato and Goldring, 1979). Failure to see dye-coupling among these cells may have related to technical aspects of dye injection (see Gutnick et al., 1981) or possibly to a state of unintentional respiratory acidosis.

Astrocytes grown *in vitro* are not always dye-coupled. A maximum of ~50% of hippocampal astrocytes (Sontheimer et al., 1991) and ~80% of optic nerve astrocytes (Sontheimer et al., 1990) are coupled. It should be borne in mind, however, that weak electrical coupling can occur without dye-coupling (e.g., Ransom and Kettenmann, 1990). In hippocampal astrocytes, the expression of Na^+ channels and the existence of dye-coupling are mutually exclusive (Sontheimer et al., 1991). Astrocytes require a nominal concentration of intracellular Na^+ for survival and Na^+ influx via Na^+ channels may provide for this (Sontheimer et al., 1994); perhaps this function is also provided by coupling, which would allow cells with Na^+ influx via other routes (Na^+-dependent transporters, etc.) to share their intracellular Na^+ with neighboring cells, obviating the need for Na^+ channels.

In the rodent central nervous system, astrocytes proliferate and differentiate in the early postnatal period (Skoff et al., 1976). Dye-coupling in both gray

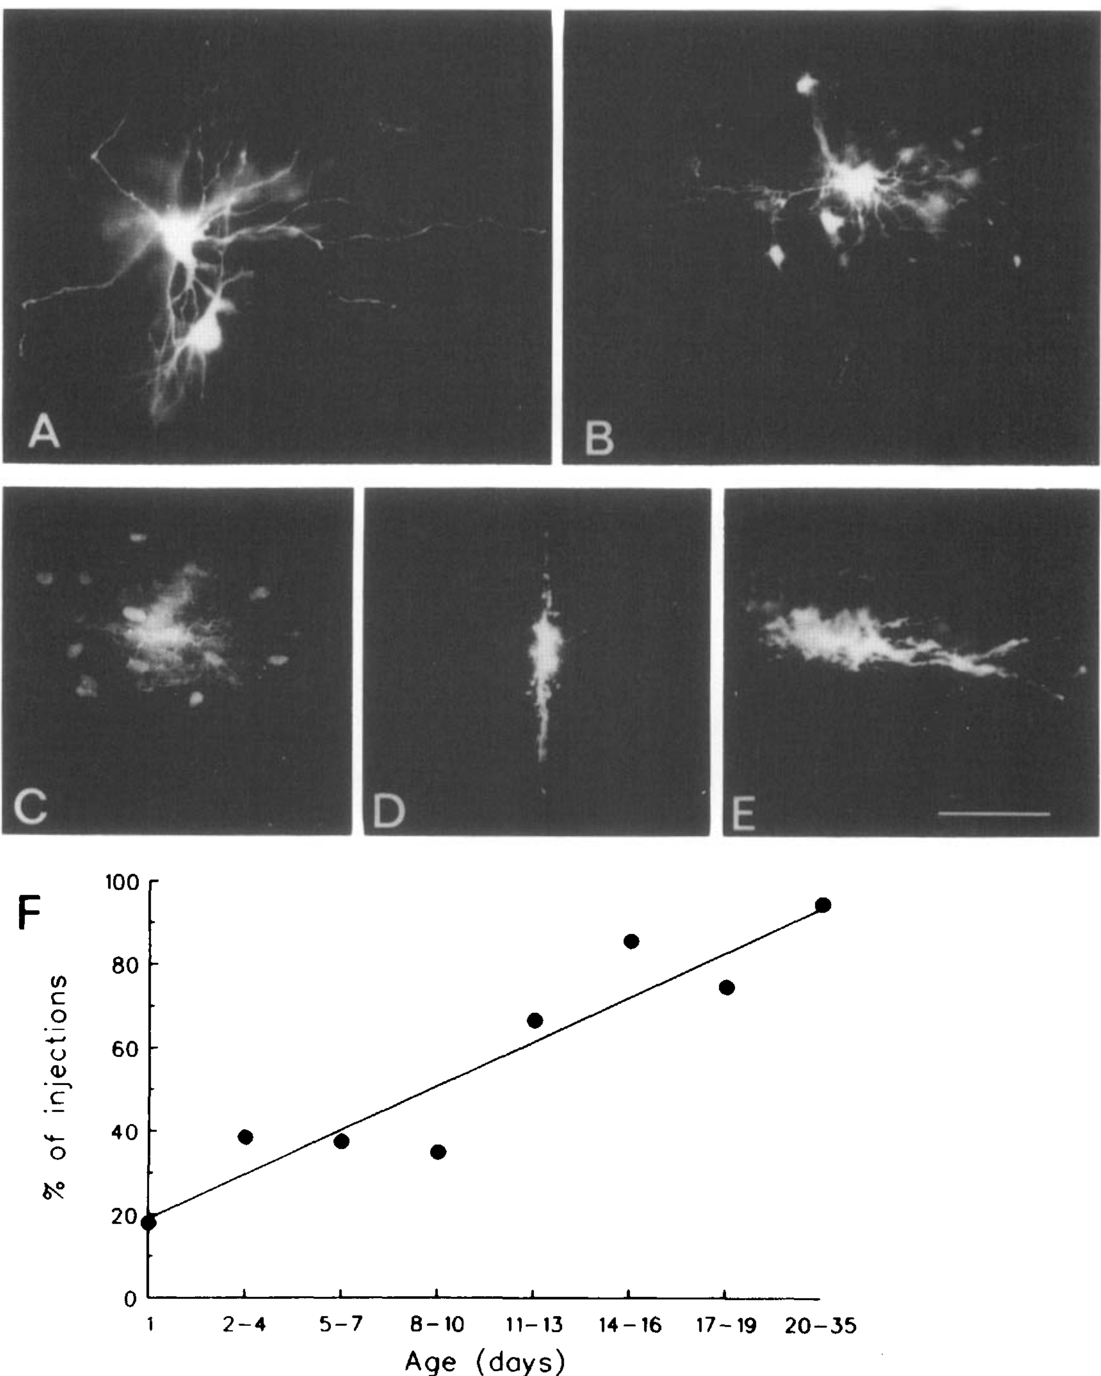

FIG. 19-5. Dye coupling in LY-filled astrocytes in white matter. Individual astrocytes in the intact rat optic nerve were injected with LY. (A, B) Mature astrocytes in the optic nerve are almost always dye coupled, occasionally to just a few cells (A), but usually to a large number of cells (B, C). Solitary astrocytes were stained following treatment with 1 μM octanol (D) or 50% CO_2 (E); these procedures are known to uncouple gap junctions. Bar in E indicates long axis of the nerve and is equal to 20 μm for A; 50 μm for B and C; and 70 μm for D and E. (F) Dye coupling between astrocytes increases with development, and 95% of LY-filled astrocytes in the mature nerve are coupled. This graph shows the percent of cell injections which resulted in multiple cell filling, as a function of postnatal age. [From Butt and Ransom (1993), with permission.]

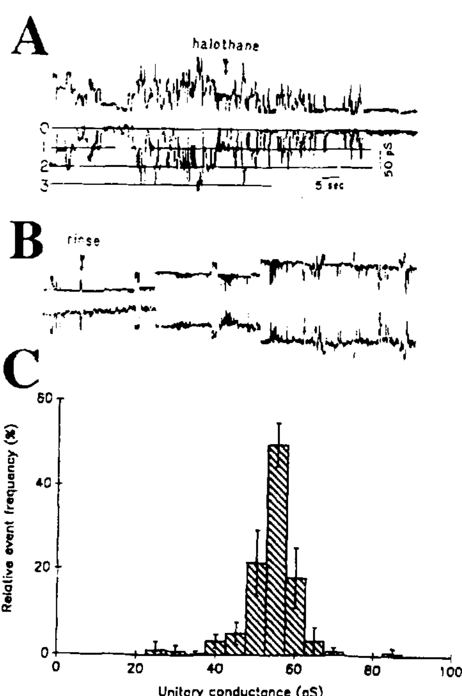
matter and white matter astrocytes develops as the cells mature, and this is seen both *in vivo* and *in vitro* (Sontheimer et al., 1990; Sontheimer et al., 1991; Binmöller and Müller, 1992; Butt and Ransom, 1993) (Figure 19-5F). The distribution of connexin43, the protein molecule that forms astrocyte gap junctions, likewise appears to increase in distribution postnatally (Dermietzel et al., 1989). This is in contrast to rat cortical neurons. These cells show intense coupling, in columnar aggregates, during early development and this progressively disappears with maturation (Lo Turco and Kreigstein, 1991).

Intercellular communication between astrocytes has been studied more quantitatively using electrophysiological methods. Most studies have used cultured astrocytes because of the technical advantage of being able to record from cell pairs under direct visual control. Rat cortical astrocytes in confluent monolayer cultures are strongly coupled electrically (Kettenmann and Ransom, 1988). All astrocytes within 300 μm of one another are coupled and the average coupling ratio (i.e., voltage change in the current-injected cell divided by the voltage change in a nearby cell) of astrocytes within 100 μm of each other is 0.44. Application of 0.5 mM Ba^{2+} or 44 mM Cs^+, ions that block K^+ conductance, depolarizes astrocytes, increases their input resistance, and dramatically increases coupling ratio; the coupling ratio is believed to increase due to an increase in the effective length constant of the glial membrane without any direct effect on junctional resistance (Kettenmann and Ransom, 1988).

The greater resolving power of the patch-clamp recording technique has been applied to the analysis of gap junctional communication between astrocytes. Pairs of adjacent astrocytes are voltage-clamped using the double whole-cell recording technique allowing the resolution of single gap junction-channel current events; the unitary conductance of single channels between astrocytes is 50 to 60 pS (Dermietzel et al., 1991; Giaume et al., 1991a) (Figure 19-6A–C). Cell pairs studied within hours after being dissociated from confluent glial cultures were strongly coupled to one another (average junctional conductance = 13 mS; Dermietzel et al., 1991). Based on a unitary junctional conductance of about 55 pS, these pairs of astrocytes appeared to be connected by approximately 235 functional gap junction channels. Gap-junctional conductance was relatively insensitive to transjunctional voltage over a range of ±50 mV (Dermietzel et al., 1991; see also Kettenmann and Ransom, 1988) but did diminish at higher transjunctional voltages (Giaume et al., 1991a). Junctional conductance was diminished by heptanol (1.5 mM), octanol (1 mM), elevated CO_2 and halothane (2 mM) (Connors et al., 1984; Dermietzel et al., 1991; Giaume et al., 1991a; Butt and Ransom, 1993). (Figure 19-5D, E and 6A, B) The ease with which octanol uncouples astrocytes appears to depend on the brain region from which the cells were derived (Lee et al., 1994); spinal cord astrocytes were the most sensitive and hippocampal astrocytes the least. In general, astrocyte gap junctions behaved similarly to gap junctions studied in other tissues where junctions are formed by connexin43 (Spray and Burt, 1990).

Within the brain, connexin43 appears to be expressed solely in astrocytes (Dermietzel and Spray, 1993). The concentration of connexin43 in the brain peaks in the early postnatal period and remains in high concentration thereafter. Strong evidence indicates that connexin43 is responsible for forming gap junctions in astrocytes (Dermietzel et al., 1989; Giaume et al., 1991a; Yamamoto et al., 1991; Dermietzel et al., 1992). The most convincing data derive from tissue culture experiments where astrocytes exhibiting functional intercellular communication express only connexin43 (Dermietzel et al., 1991; Giaume et al., 1991a). Connexin43 appears to be distributed in a plaquelike manner between astrocytes, as well as being located in the cytoplasm (Figure 19-6D, E). Ultrastructural analysis shows that connexin43 is, indeed, associated with the gap junctional complex itself (Dermietzel et al., 1991; Giaume et al., 1991a). A possible discrepancy in the association of connexin43 with astrocytic coupling has arisen with reactive astrocytes in the kainate-lesioned hippocampus. These cells exhibit robust dye-coupling (Burnard et al., 1990), in spite of the fact that connexin43 is apparently reduced in kainate-induced areas of gliosis (Vukelic et al., 1991).

Connexin43 appears to be widely distributed throughout the mammalian brain, although some areas show a higher concentration of the protein than others (Batter et al., 1992; Nagy et al., 1992). The concentration of connexin43 protein, cellular immunoreactivity and mRNA expression is four times greater in cultured astrocytes derived from hypothalamus compared to striatum. Furthermore, the hypothalamic astrocytes are more highly coupled than those from the striatum (Batter et al., 1992; see also Lee et al., 1994). Connexin43 is least expressed in spinal white matter (Nagy et al., 1992). The ratio of phosphorylated to nonphosphorylated forms of connexin43, believed related to the functional state of the protein, is constant from region to region (Batter et al., 1992; Nagy et al., 1992). These findings suggest that the strength of astrocyte intercellular communication varies with brain region and that this difference is controlled at



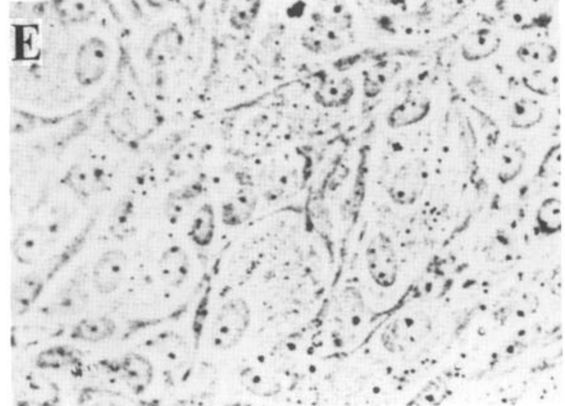


FIG. 19-6. Electrophysiological and molecular characteristics of rat forebrain astrocytes in culture. Pairs of astrocytes are recorded from using the double whole-cell recording technique. The two traces show the junctional current recorded in each astrocyte and the abrupt fluctuations represent openings and closings of individual gap junction channels. Voltage of the upper cell of the pair is held at 0 mV and voltage of the lower cell at −50 mV. Calibration bar represents 2.5 pA and corresponds to 50 pS. Application of halothane (1 μM) causes a decline in junctional current, which is reversible when the halothane is removed (B). (C) The frequency distribution of the unitary conductances of single gap junction channels is shown. The vast majority of these unitary conductances fall between 50 and 60 pS. (D) Immunohistochemical localization of anticonnexin43 immunoreactivity in 3-week-old astrocyte cultures derived from rat cortex and striatum. The connexin43 protein appears to be located in plaquelike areas between cells (*arrows*) as well as within the cytoplasm (*asterisks*). (E) A phase-contrast micrograph shows the cells in "D". ×700. [From Dermietzel *et al.* (1991), with permission.]

the level of gene expression. The functional significance of regional differences in astrocyte coupling, in the larger context of brain function, is not known.

Norepinephrine, apparently acting through a second-messenger pathway, downregulates functional gap junctional communication between striatal astrocytes (Giaume et al., 1991b). The norepinephrine effect may be mediated by activation of phospholipase C. Elevating cAMP by application of the beta-adrenergic agonist isoproterenol enhances dye-coupling (Giaume et al., 1991b). It was recently reported that astrocyte dye-coupling is increased by application of glutamate or high [K^+] solutions (Enkvist and McCarthy, 1994); brief applications of high [K^+] solutions did not increase coupling between oligodendrocytes and astrocytes (Ransom and Kettenmann, 1990). Glutamate or high [K^+] solution cause membrane depolarization and this might be linked to changes in coupling via changes in intracellular pH (Ransom, 1992). Depolarization produces an alkaline shift in astrocytes that could enhance coupling (Ransom, 1992). The effects of pH on coupling can be persistent; intracellular acidification mediated by lactate results in irreversible uncoupling if the acidification persists for thirty minutes (Anders, 1988).

Oligodendrocytes. Myelinating oligodendrocytes in situ, typically (i.e., 75% of fills) show dye-coupling to other oligodendrocytes (Butt and Ransom, 1989; Butt and Ransom, 1993) (Figure 19-7). The number of dye-coupled cells is small, usually between two and four, and coupling appears to occur at contacts

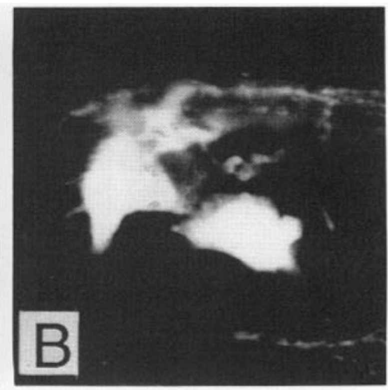

FIG. 19-7. Dye-coupling between mature oligodendrocytes in the intact rat optic nerve. Injection of LY into individual oligodendrocytes frequently resulted in the staining of two or more cells as seen here (A). The dye-coupled cells are easily recognized as oligodendrocytes because of their unique longitudinal processes (see Ransom et al., 1991). At higher magnification, closely adjacent dye coupled cell bodies can be seen (B). Bar in A indicates long axis of the nerve and = 50 μm in A and 20 μm in B. [From Butt and Ransom (1993), with permission.]

between adjacent cell bodies (Butt and Ransom, 1993). Oligodendrocytes in the rabbit retina also show dye-coupling (Robinson et al., 1993), but immature oligodendrocytes in mouse corpus callosum are not dye-coupled (Berger et al., 1991), perhaps related to their immaturity. Immature oligodendrocytes rarely show dye- or electrical coupling, but coupling gradually increases in frequency as the cells mature (Figure 19-8C) (Blankenfeld, et al., 1993).

Oligodendrocytes derived from mouse spinal cord and studied *in vitro,* show electrical coupling in about 75% of cell-pairs tested (Kettenmann et al., 1983; Kettenmann and Ransom, 1988). The coupling between oligodendrocytes is less intense than between astrocytes; coupled oligodendrocytes within 100 μm of each other have an average coupling ratio of 0.11. As with astrocytes, the application of either Cs^+ or Ba^{2+} enhances electrical coupling and allows it to be recognized between cell-pairs that were judged not to be coupled in control solution (Kettenmann and Ransom, 1988) (Figure 19-8D). Oligodendrocytes therefore appear to be widely coupled by junctions that allow only weak electrical interaction, in accordance with the ultrastructural observation that interoligodendrocytic gap junctions are much less frequent than gap junctions between astrocytes (Massa and Mugnaini, 1985).

Using the double whole-cell recording technique, the mean junctional conductance between coupled mouse oligodendrocytes is 2.7 nS (Blankenfeld et al., 1993) (Figure 19-8A, B). If each gap channel between oligodendrocytes has a mean conductance of 120 or 150 pS (Dermietzel et al., 1993; see below), the estimated number of channels forming junctions between oligodendrocytes would range from 10 to 30. Electrical coupling between oligodendrocytes is reversibly blocked by intracellular acidification (Kettenmann et al., 1990). To achieve uncoupling, however, intracellular pH has to be decreased to below 6.5 and this could only be achieved if the dominant pH_i regulating mechanism in these cells, the Na^+-HCO_3^- cotransporter, was blocked (Kettenmann et al., 1990).

In contrast to astrocytes, oligodendrocytes appear to express connexin32 *in situ* (Dermietzel et al., 1989). The level of connexin32 expression is less than that of connexin43 consistent with the less abundant gap junctions between oligodendrocytes (e.g., Massa and Mugnaini, 1985) and their weaker functional coupling (Kettenmann and Ransom, 1988). Details regarding the single-channel characteristics between oligodendrocytes are not yet available, but, based on the behavior of connexin32 in expression systems, it is likely that single-channel conductance is ~120 to 150 pS. These channels show somewhat greater sensitivity to transjunctional voltage than channels formed from connexin43 (Bennett et al., 1991).

Gap junctions are frequently observed ultrastructurally between astrocytes and oligodendrocytes (Massa and Mugnaini, 1985; Mugnaini, 1986). Consistent with this, intercellular coupling between astrocytes and oligodendrocytes has been demonstrated *in vitro* (Ransom and Kettenmann, 1990) and *in situ* (Robinson et al., 1993). In comparison to the strength of coupling between astrocytes and between oligodendrocytes, electrical coupling between astrocytes and oligodendrocytes is weak (Ransom and Kettenmann, 1990) (Figure 19-9). The average coupling ratio for cells within 100 μm of one another is 0.04. Under optimal conditions for the detection of coupling (i.e., in the presence of Ba^{2+} or Cs^+

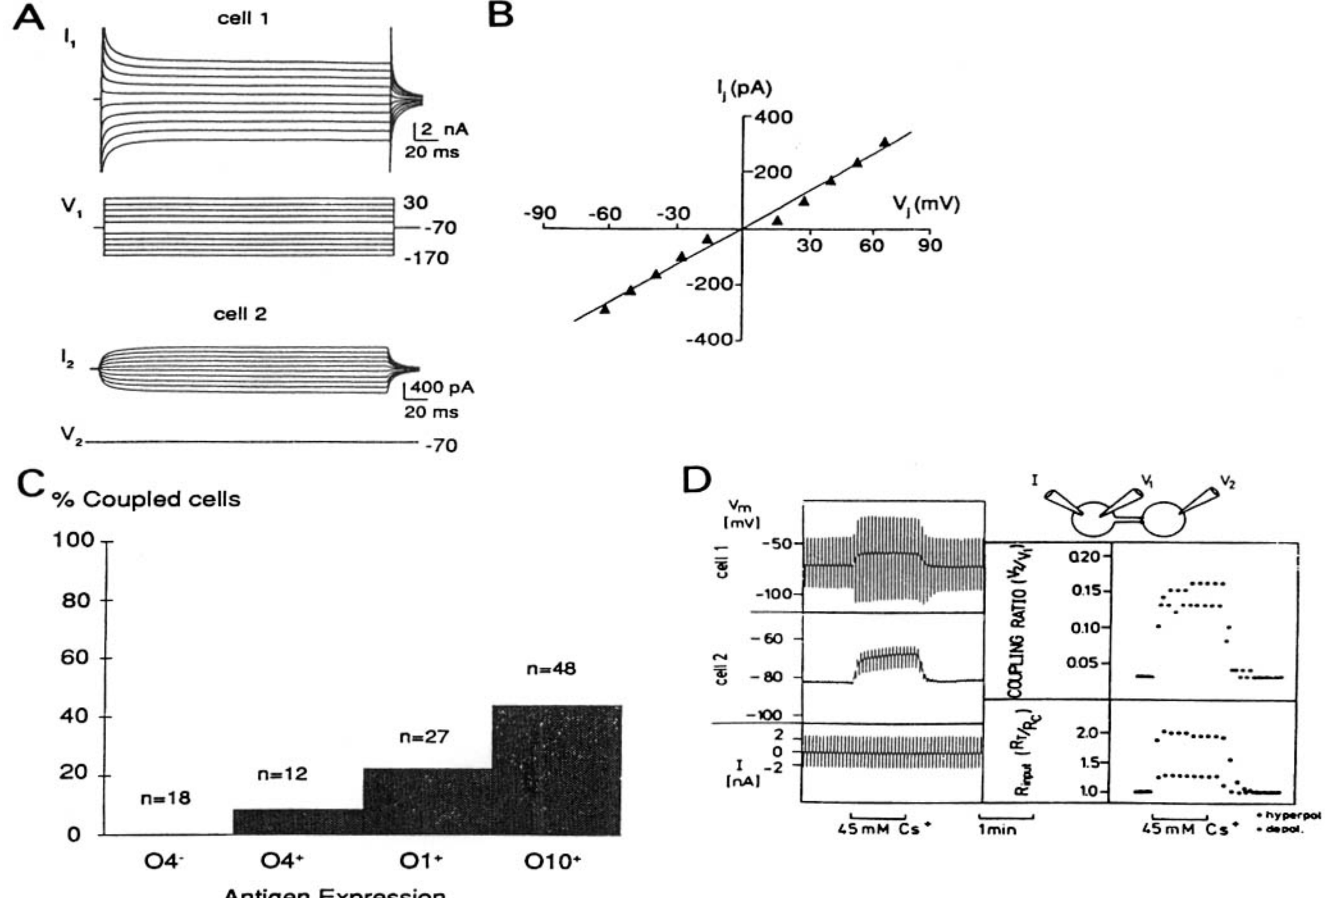

FIG. 19-8. Characteristics of dye and electrical coupling between cultured oligodendrocytes. (A) Two adjacent mature oligodendrocytes are voltage-clamped using the double whole-cell patch clamp configuration. In one cell of the pair the voltage is stepped between −170 and +30 mV (V_1). The second cell is kept at −70 mV (V_2). The currents resulting from these voltage steps are shown for both cells. (B) Based on the measurements made in A, the current flowing across the gap junctions between these cells, I_j, can be calculated and is plotted as a function of transjunctional voltage (V_j). The gap junctional conductance estimated from this relationship is 4.2 nS. (C) Coupling between oligodendrocytes increases with maturation as defined by the expression of stage specific antigens; immature oligodendrocytes express O4 and only mature oligodendrocytes express the O10 antigen. [From Blankenfeld et al. (1993), with permission.] (D) Cesium (Cs^+) increases coupling ratio in oligodendrocytes. Coupling is monitored by injecting current pulses (I) into one oligodendrocyte while recording membrane potential (V_m) in the same cell (cell 1) and in an adjacent oligodendrocyte (cell 2). Application of Cs^+ (substituted for Na^+) reversibly increases coupling ratio. Cs^+ blocks resting K^+ conductance (note increase in input resistance) and is believed to increase coupling ratio by increasing the effective length constant of the glial membrane without any direct effect on junctional resistance. Solid circles are measurements from depolarizing pulses and open circles are measurements from hyperpolarizing pulses. [From Kettenmann and Ransom (1988), with permission.]

which increases coupling ratio three- to fivefold), coupling is seen in about 80% of the contiguous cell pairs tested (Ransom and Kettenmann, 1990). In rabbit retina, dye is able to flow more freely from astrocytes into oligodendrocytes than from oligodendrocytes into astrocytes (Robinson et al., 1993). This interesting observation of unidirectional coupling, or "chemical rectification," may be the consequence of a gap junction composed of two hemiconnexons, each composed of a different connexin, namely, connexin43 in the astrocyte and connexin32 in the oligodendrocyte. It is not clear if unidirectional coupling is a general feature of astrocyte-oligodendrocyte junctions, but to the extent that it is, it suggests the possibility of a hierarchical arrangement for the flow of some metabolic signals (Robinson et al., 1993).

Other Glial Cells. As mentioned above, Schwann cells exhibit coupling which disappears when they begin to make myelin (Konishi, 1990). These junctions are probably mediated by connexin32 (Bergoffen et al., 1993), which continues to be expressed in Schwann cells in mature myelinated rat sciatic nerve, but is confined to the paranodal regions and

Schmidt-Lanterman incisures. This pattern suggested that gap junctions may connect the paranodal folds of myelinating Schwann cells, perhaps facilitating ion and small molecule movements to and from the tight, periaxonal space. The X-linked form of the hereditary neuropathy known as Charcot-Marie-Tooth disease, is associated with mutations in the connexin32 gene (Bergoffen et al., 1993). These observations indicate that gap junction protein expressed in Schwann cells plays a critical role in peripheral nerve integrity and function.

Ependymal cells, specialized glia which line the ventricles, have gap junctions and exhibit physiological properties that are similar to other glial cells (Connors and Ransom, 1987; Jarvis and Andrew, 1988; see also Ransom and Carlini, 1986). Turtle ependymal cells are extensively coupled to one another and are uncoupled by exposure to elevated CO_2 (Connors and Ransom, 1987). Similar observations have been made for ependymal cells in the rat third ventricle, but these cells seemed resistant to uncoupling by intracellular acidification (Jarvis and Andrew, 1988). Gap junctions in ependyma are constructed of connexin26 and connexin43 (Dermeitzel et al., 1989).

As discussed above, nonmammalian Müller cells, but not mammalian Müller cells, exhibit gap-junctional communication. Müller cells in the salamander retina show strong coupling to one another with coupling ratios as high as 0.2 at distances of 200 μm. Theoretical calculations indicate that electrical coupling in this system may significantly contribute to lateral movement of accumulated K^+ within the retina (Mobbs et al., 1988).

Bergmann glial cells of the cerebellum, are coupled to each other *in situ* (H. Kettenmann, personal communication). Recently, glial cells of the intermediate lobe of the pituitary, called stellate glia, were found to be strongly coupled to one another (Mudrick-Donnon et al., 1993). These cells also receive synaptic-like contacts from neurons, and the fascinating observation was made that they exhibit stimulus-evoked synaptic-like potentials mediated by the inhibitory transmitter GABA.

Functions of Gap Junctions

Several functions have been proposed for gap junctions based on their physiological properties (Loewenstein, 1981; Caveney, 1985; Bennett et al., 1991). They may serve to coordinate the electrical and metabolic activities of cell populations, act to amplify the consequences of signal transduction, control intrinsic proliferative capacity and help to orchestrate the complex events of embryonic morphogenesis. In some tissues, but not in others, the practical significance of intercellular coupling is clear. For example, the coordinated contraction of the heart, critical for its function as a pump, is mediated by rapid transfer of voltage signals via gap junctions between individual heart cells (Loewenstein, 1981). We do not, however, have detailed information about how coupling contributes to the functions of glial cells, but plausible hypotheses may be formulated that are variations on the general themes listed above. The robust and selective expression of coupling in glial cells suggests that intercellular communication is of major importance for the functioning of these cells within the brain.

The pattern and strength of coupling among different types of glial cells should be born in mind as possible functions of these cells are discussed. Available evidence indicates that astrocytes are strongly coupled to one another, while coupling between oligodendrocytes is weak, and heterologous coupling between astrocytes and oligodendrocytes is weaker still (Figure 19-9). Astrocytes, therefore, are likely to participate more vigorously than oligodendrocytes in most of the functions related to intercellular coupling. The geometry of coupling among cells could be important in determining function. For example, astrocytes in certain areas of the brain might be cou-

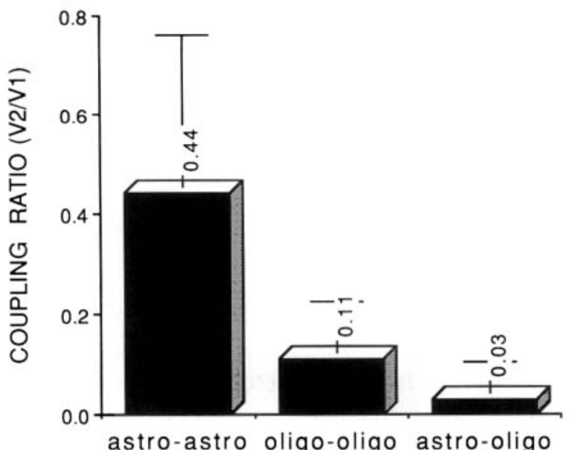

FIG. 19-9. Comparison of homogolous and heterogolous glial coupling. The mean coupling ratios are shown for oligodendrocyte pairs, astrocyte pairs, and astrocyte-oligodendrocyte pairs. All the cell pairs are within 100 μm of each other. Cell pairs which failed to show coupling have been excluded, since coupling ratio cannot be calculated under this circumstance. [From Ransom and Kettenmann (1990), with permission.]

pled in nonrandom patterns conferring a directional preference on intercellular communication. Thus far, such patterns have not been detected *in situ* (Gutnick et al., 1981; Binmöller and Müller, 1992), but this remains an open question. Propagating waves of Ca^{2+} increase in astrocytes (see below), stimulated by glutamate, seem to move in a nonuniform fashion through astrocytic monolayers, suggesting that this signal may follow specific pathways through coupled glial aggregates (Finkbeiner, 1993). The significance of coupling between astrocytes and oligodendrocytes remains obscure. Astrocytic processes which project to nodes of Ranvier, called *perinodal astrocytes*, are frequently connected by gap junctions to the terminal paranodal loops of nearby myelinating oligodendrocytes (Black and Waxman, 1988). This specialized arrangement could mediate an axon-specific type of K^+ spatial buffering (see below). To move beyond mere speculation, however, more information is needed about the relative strengths and patterns of intercellular communication among glial cells *in vivo*.

Potassium Ion Spatial Buffering and Extracellular Potential Generation. Astrocytes exhibit strong electrical coupling to one another, which may assist K^+ spatial buffering and the generation of extracellular potentials. The K^+ spatial buffer hypothesis states that glial cells participate in moving extracellular K^+ from areas where it accumulates secondary to neural activity, to distant areas where the K^+ is not elevated (Orkand et al., 1966; Chapter 37, this volume). This hypothesis remains attractive, but its quantitative significance has been difficult to establish (Ransom and Carlini, 1986; Sykova, 1983; Karwoski et al., 1989; Chapter 37, this volume). Strong astrocytic coupling would extend the distance over which this K^+ distribution system could operate and, perhaps, increase its efficiency (Orkand, 1986; Mobbs et al., 1988). Some experimental evidence supports this notion. In the isolated frog spinal cord, massive increases in P_{CO_2}, which presumably uncoupled glial cells due to intracellular acidification (but see Kettenmann et al., 1990), slowed the clearance of neural activity-induced increases in K^+ (Sykova et al., 1988).

Another mechanism whereby glial cells may participate in buffering the extent of K^+ accumulation occurring with neural activity, is by direct uptake and sequestration of K^+ (Coles and Tsacopoulos, 1979; Ransom and Carlini, 1986; Ballanyi et al., 1987). This process might also benefit from glial coupling because the coupled glial aggregate would have a larger intracellular volume to buffer against changes in intracellular K^+ concentration that could occur with K^+ uptake. This would be desirable because the K^+ uptake system (e.g., passive KCl uptake and/or KCl cotransport and/or Na^+-K^+ ATPase; see Ransom and Carlini, 1987; Chapter 18, this volume) would tend to function better against a lower K^+ concentration gradient.

It is well established that glial cells participate in the production of extracellular field potentials seen with neural activity (Ransom and Carlini, 1986; Ransom, 1974; Somjen, 1970). This has been most elegantly studied in the mudpuppy optic nerve, where the consequences of direct glial depolarization on surface potential can be quantitatively analyzed (Cohen, 1970). It is apparent from this work that interglial coupling is critical for determining the distribution of extracellular field potentials (Cohen, 1970). Glial-generated field potentials may influence neural integration, but the magnitude of such effects is unknown (see Somjen, 1973).

Intracellular Metabolic Homeostasis. The best understood role of gap-junctional communication is to provide for synchonization and propagation of electrical activity in certain excitable cells, namely, heart and smooth muscle cells, and some neurons (Loewenstein, 1981). In nonexcitable cells, gap junctions may be more important for metabolic coordination within the coupled aggregate. In the case of cells that are strongly coupled, uniform distributions of ions and small molecules are ensured, and cellular variations in the concentrations of junction-permeant molecules will be buffered. For example, frog skin cells exhibit similar Na^+ concentrations when the cells are coupled, but the concentrations diverge when the cells are uncoupled (Rick et al., 1981). Gap junctions, therefore, can cause a group of individual cells to function almost as one in terms of metabolism and membrane potential (Figure 19-10A).

The capacity for small molecules to diffuse freely between coupled glial cells has several theoretical advantages. Glial cells have high affinity uptake systems for a number of neurotransmitters (Chapter 48, this volume). Under normal conditions, transmitters are released focally at synaptic sites and transported across immediately adjacent glial membranes, which constitute only a small fraction of a given glial cell's total surface area. The rate of transmitter uptake will depend, among other things, on the transmembrane gradient for this molecule. Strong glial coupling, by providing a larger effective intracellular volume, would prevent large changes in the intracellular concentration of the transmitter from occurring with uptake, maximizing the efficiency of this process.

Conversely, transmitter molecules can also be re-

leased from glial cells, although the functional significance of this is poorly understood (Chapter 48, this volume). Release from glial cells is nonvesicular and will depend, in part, on the intracellular concentration of the transmitter. Coupling among glial cells would ensure relatively stable intracellular levels of various transmitter molecules, and ensure uniformity of the release process.

Genetically aberrant cells incapable of manufacturing certain metabolites can survive by receiving the metabolite in short supply via gap junctions with healthy neighboring cells (Loewenstein et al., 1981). At present, this remains only a speculative possibility for glial cells.

Signal Transfer. Recently a novel form of cellular response has been identified that consists of a propagating wave of cytoplasmic Ca^{2+} increase (Finkbeiner, 1993; Chapter 17, this volume). Waves of cytoplasmic Ca^{2+} increase are readily elicited in astrocytes by glutamate application. The waves move through individual cells at a constant velocity and follow a somewhat curvilinear course. Functional gap junctions are necessary for the intercellular propagation of glutamate-induced Ca^{2+} waves (Finkbeiner, 1993). Current evidence suggests that intercellular propagation of Ca^{2+} waves is mediated by the movement of inositol 1,4,5-trisphosphate (IP_3) through gap junctions (Boitano et al., 1992); Ca^{2+} is then released from intracellular stores by the traveling wave of IP_3. The functional importance of this intriguing long-range signaling system in astrocytes is unknown, but it depends on gap-junctional communication.

Another functional consequence of intercellular coupling is divergence of signal transmission (Figure 19-10B). Consider the case of a cell stimulated to produce an intracellular second messenger molecule (e.g., cAMP, IP_3, Ca^{2+}) by binding a specific ligand. If the cell is not connected to its neighbors by gap junctions, it will act in isolation. But if the cell is

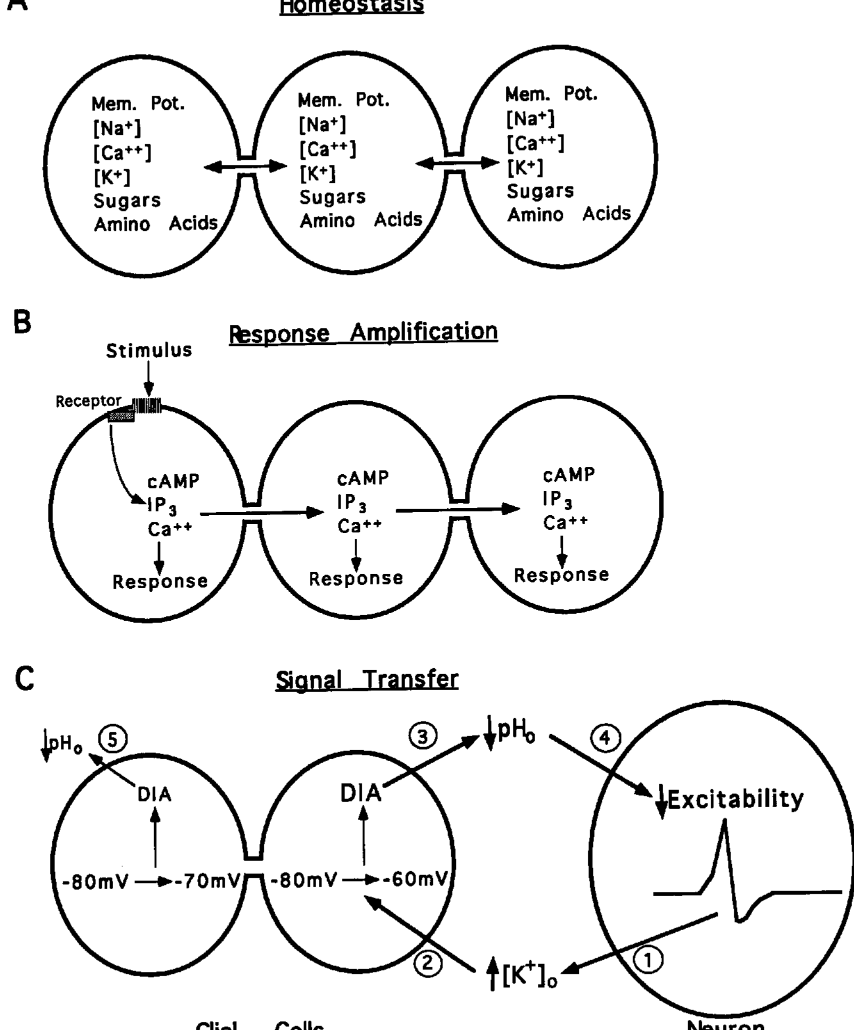

FIG. 19-10. Schematic illustration of some of the possible functions of intercellular communication. (A) In strongly coupled cell aggregates, the intracellular concentrations of ions and molecules less than ~1,000 kD in size (including amino acids, sugars, and second-messenger molecules) will tend to be similar due to free exchange across gap junctions. This will cease to exist if "gating" conditions favor closure of gap channels; pathological circumstances such as anoxia may lead to rapid uncoupling because of increases in intracellular Ca^{2+} and H^+. (B) Coupling can amplify the physiological consequences of a chemical stimulus (i.e., hormone, neurotransmitter, etc.) acting on a single cell. Such stimuli often cause the production of second messenger molecules (i.e., Ca^{2+}, IP_3, cAMP) that can move easily into adjacent cells via gap junctions; the coupled cells are then recruited to respond. (C) Schematic illustration of a hypothesized neuronal-glial interaction mediated by pH_0 (Ransom, 1992). Active neurons cause an increase in $[K^+]_0$ (*1*), which causes depolarization (*2*) leading to depolarization-induced-alkalinization (*DIA*). The glial DIA causes an acid shift in pH_0 (*3*) that decreases the excitability of nearby neurons (*4*). Distant glial cells that are coupled by gap junctions to glia in the immediate vicinity of the active neurons, also experience the depolarization "signal," but less strongly. These distal cells then weakly acidify their environment (*5*), perhaps producing reduced excitability in the neurons that surround the actual area of elevated $[K^+]_0$ (Ransom, 1992). [Figure C modified from Ransom (1992), with permission.]

widely coupled to other cells, the diffusable, junction-permeable second messenger (Saez et al., 1989) has the potential of activating many cells (Loewenstein, 1981).

Kuffler and his colleagues speculated that K^+ accumulating in brain extracellular space with neural activity might act as a signal to glial cells because these cells responded to K^+ with graded membrane depolarization (Orkand et al., 1966; Kuffler and Nicholls, 1967; Chapter 31, this volume). Recent observations suggest that this local "signal" may cause an extracellular acid shift that is mediated by depolarization of glial cells (Ransom, 1992). The glial-mediated acid shift, in turn, may modulate ongoing neural activity. This hypothesized neuronal-glial interaction can potentially be amplified by glial coupling as shown in Figure 19-10C. The presence of strong coupling would be predicted to produce a larger area of extracellular acidification and thereby a larger area of neural modulation (Ransom, 1992).

Proliferative Activity and Development. The role of gap-junctional communication during development has been discussed at length (e.g., Caveney, 1985). Embryos exhibit widespread gap-junctional communication, which may be important in establishing developmental fields critical for morphogenesis. Until more is known about the molecules that direct early development, however, specifically if they are junction-permeable, this attractive hypothesis remains difficult to test. Developing rat cortical neurons are transiently coupled to each other in columnar groups, and it is hypothesized that this coupling may play a role in determining the functional organization of the cortex (Lo Turco and Kriegstein, 1991). Coupling between glial cells develops as these cells mature, and would not, therefore, play a role in early glial development. Conceivably, coupling might be related to the determination, and perhaps maintenance, of final cellular phenotype.

Considerable circumstantial evidence indicates that gap-junctional communication can act to restrict cell proliferation (Loewenstein, 1981). Most malignant cell populations show no intercellular coupling (Loewenstein, 1981; Klaunig and Ruch, 1990; Bennett, et al., 1981). The mechanism by which gap-junctional coupling might serve to suppress mitotic activity is presently unknown. Because the majority of primary brain tumors are glial in origin, the possibility that loss of gap junctions in these cells leads to neoplastic transformation is intriguing. The observation that C6 glioma cells fail to exhibit gap junctions is consistent with this idea (Naus et al., 1993), as is the observation that highly malignant human gliomas lack gap junctions (Tani et al., 1973). More work will be necessary to properly test the importance of intercellular communication as a regulator of proliferation in glia.

CONCLUSIONS

Gap junctions and the special form of intercellular communication which they mediate, have been extensively investigated in the last quarter century since their discovery. Our knowledge about gap junctions is impressive but incomplete. This is especially so in the brain, where these junctions are widely expressed in glial cells, but we lack conclusive insight about how they participate in brain function. The situation, however, should be viewed optimistically because gap-junctional communication among glial cells has been sufficiently well characterized that reasonable hypotheses about their function can now be formulated and tested. Research prospects in this area are also brighter due to the availability of important new information about the molecular biology of gap junctions, which places in our hands powerful tools for further experimental analysis.

20 Electrophysiology of mammalian glial cells *in situ*

GEORGE G. SOMJEN

Experiments on invertebrate neuroglia and on glial cells in culture have yielded many exciting discoveries that radically changed our conception of the place of these cells in general biology. The newly found wealth of receptors and ion channels expressed in the membrane of glial cells in such systems is described elsewhere in this volume. In this chapter the focus is on the electrophysiological responses of neuroglia manifested *in situ* in the central nervous system (CNS) of mature mammals. In experiments with intact central nervous system tissue, the gap between the ideal and the practical is usually greater than it is in experiments on model systems such as cell cultures or invertebrate ganglia. Still, in spite of technical difficulties, our understanding of mammalian glial cells would be incomplete without observing them in their natural habitat, under as nearly physiological conditions as is technically feasible.

The scope of this chapter, then, is limited. It covers only electric responses of mammalian glial cells as seen either in intact CNS or in those isolated tissue preparations that have been freshly dissected from mature CNS with their cytoarchitecture more or less preserved. Inclusion of data from brain tissue slices seems justified in the light of the similarity of glial cell responses in such preparations to those in intact brain (Schwartzkroin and Prince, 1979; Casullo and Krnjević, 1987). The early literature on glial electrophysiology has been repeatedly surveyed (Kuffler and Nicholls, 1966; Kuffler, 1967; Somjen, 1975; Somjen, 1980; Somjen, 1987), and only the most relevant contributions are summarized here. Inevitably, this chapter overlaps to some degree with Chapters 11, 12, 18, 19, 31, and 47 and perhaps others in this volume. My goal is to avoid undue repetition yet present a cohesive essay that may be readable by itself. Therefore, areas in common with others will be included insofar as is necessary to present the main topic coherently.

MEMBRANE POTENTIAL RESPONSES OF GLIAL CELLS

Investigation of the cellular electrophysiology of the mammalian central nervous system began with the invention of intracellular recording, applied first to cat spinal cords (Brock et al., 1952), then to other regions. Nerve cells were hunted in blind searches with microcapillary electrodes in the depth of gray matter. Sometimes, instead of the sought-after neurons, cells were encountered that generated neither action potentials nor synaptic potentials (Phillips, 1956). Various authors called these cells "inexcitable," "silent," "unresponsive," *stumm* (=mute) and "idle." While careful not to commit themselves, most workers suspected that they were glia (e.g., Phillips, 1956; Sugaya et al., 1964; Krnjević and Schwartz, 1967; Glötzner and Grüsser, 1968). Eventually they were identified as such by *intra vitam* intracellular marking with dye followed by *post mortem* histology (Kelly et al., 1967; Grossman and Hampton, 1968; Kelly and Van Essen, 1974).

But as it turned out, glial cells are electrically not completely unresponsive after all. Sugaya et al. (1964) were the first to notice that the membrane potential of "idle" cells actually does change during neuronal excitation. They reported in 1964 that during seizure discharges and during spreading depression these cells underwent slow depolarization.

These early encounters with presumed glial cells were usually accidental. The first deliberately planned study of "idle" units in cerebral neocortex was probably by Karahashi and Goldring in 1966. They reported that repetitive stimulation of the cortical surface, or of an afferent pathway, caused a depolarizing shift of the membrane potential of these cells, which they believed could either be glia, or neuron dendrites, or nonspiking neurons. Single volleys, which did evoke sizable neuronal responses, had no effect on the "idle" cells. These observations were soon confirmed by others (Glötzner and Grüs-

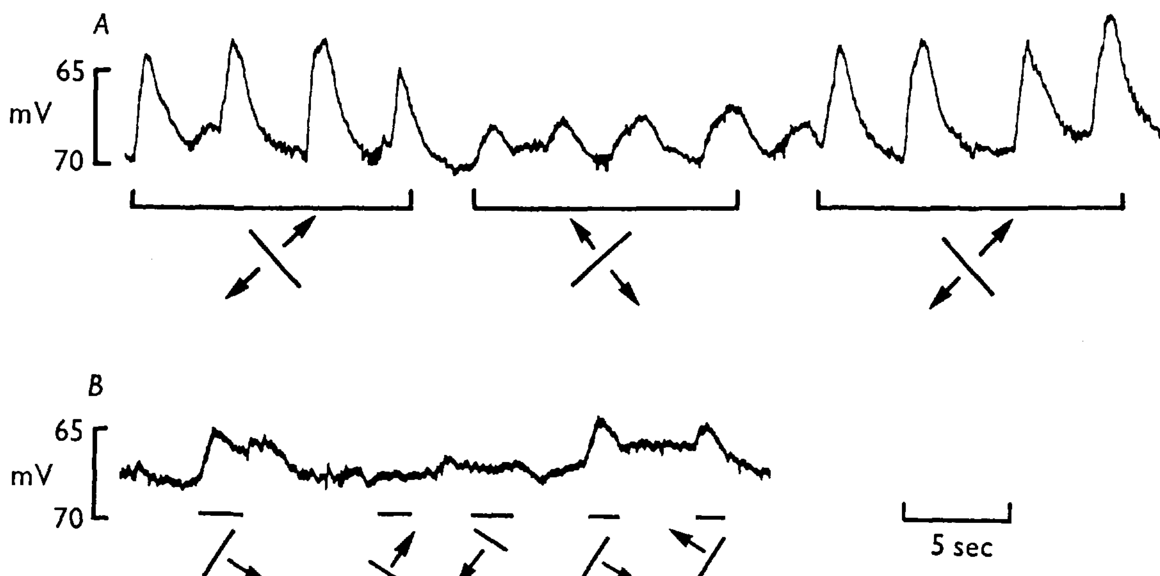

FIG. 20-1. Responses of cortical cells evoked by physiological (adequate) stimulation of sense organs. (A, B) Two glial cells, both in primary visual receiving area of the cerebral cortex of an anesthetized cat. The *insets* show the orientation and direction of the movement of the visual stimulus, which was a slit of light projected on a screen in the animal's visual field. The largest depolarizing responses are evoked by the stimulus oriented optimally for excitation of the neurons located in the same cortical column. [From Kelly and Van Essen (1974), with permission.]

ser, 1968; Grossman and Hampton, 1968; Sypert and Ward, 1971; Dichter et al., 1972; Ransom and Goldring, 1973b; Ransom, 1974). That not only electrical stimulation, but also more natural, adequate sensory stimulation, can evoke slow depolarizing responses was first reported by Kelly and Van Essen (1974). In these experiments the cells were marked by dye injected *in vivo* and their identity as glia was confirmed by histology *post mortem*. The now classical illustration of their responses is reproduced as Figure 20-1.

Slow depolarization during repetitive orthodromic stimulation was also recorded in spinal cord from "unresponsive" cells that were assumed to be glia

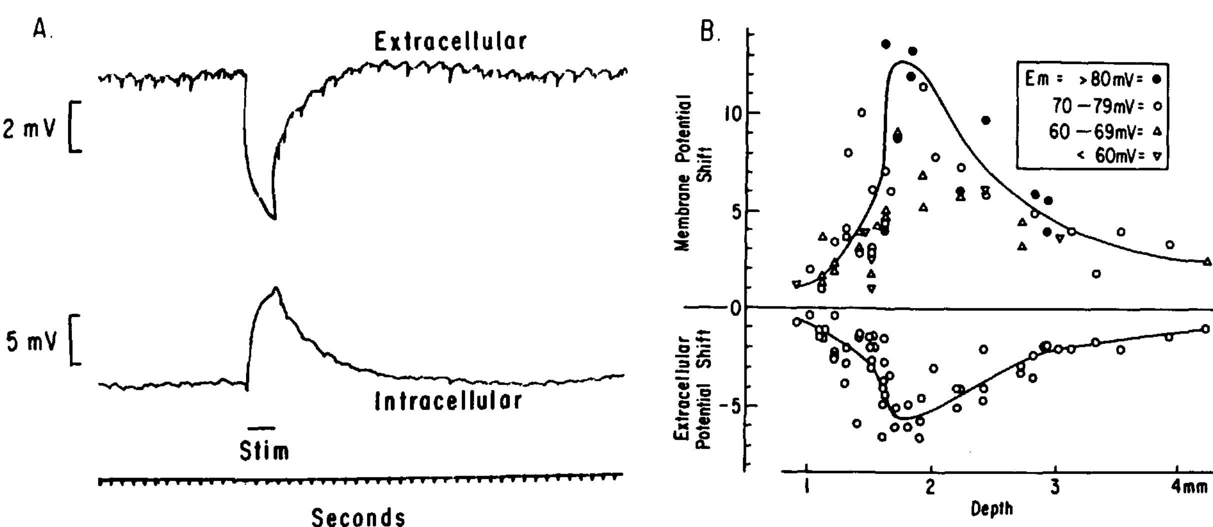

FIG. 20-2. Responses of glial cells and simultaneously recorded extracellular sustained potential shifts (ΔV_0) in spinal gray matter of cats. (A) Sample recordings made with twin microelectrodes fastened together so that the tips lay not more than 50 μm apart. Horizontal bar marks repetitive simulation of the dorsal root. (B) Amplitude of the responses evoked by identical trains of pulses in 7 cats. The abscissal scale shows depth from the dorsal surface of the spinal cord. The *inset* indicates the ranges of the resting potentials of the glial cells. [From Somjen (1970), with permission.]

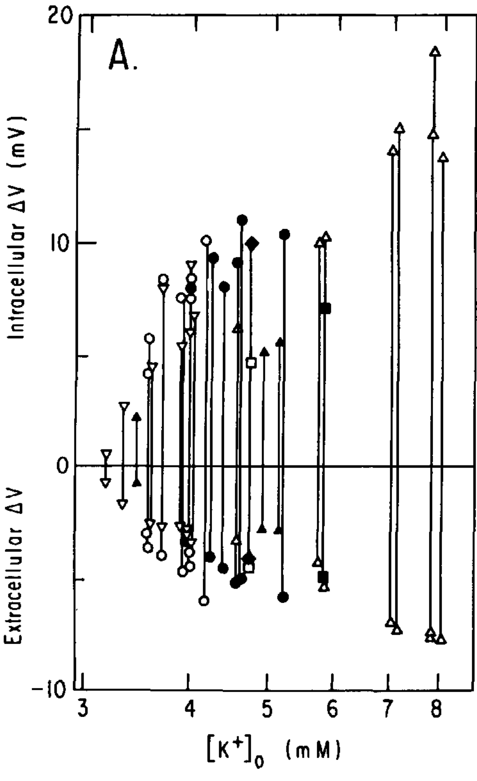
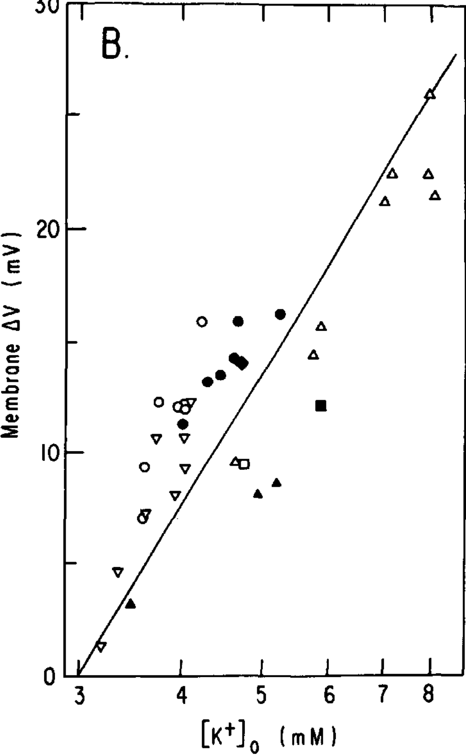
(Somjen, 1969, 1970) (Figure 20-2). The depolarization of presumed glial cells differed from the synaptic potentials of neurons not only in the much slower time-course, but also in that it was not associated with a change of input resistance (Somjen, 1970). The same lack of change in input resistance was also noted for cortical glial cells (Sypert and Ward, 1971; Ransom and Goldring, 1973b). The slow depolarization of spinal and cortical glial cells resembled closely the responses recorded in glia of leech and amphibia by Kuffler and associates (Orkand et al., 1966; Kuffler and Nicholls, 1966; Kuffler, 1967). These authors found that depolarization of glial cells of cold-blooded animals was caused by the rise of extracellular potassium concentration ($[K^+]_0$), due to the release of K^+ ions from excited neurons. The membrane of these cells behaved as a "perfect K^+-electrode," and it had a constant ohmic resistance that showed no voltage-dependent changes (Orkand et al., 1966; Kuffler and Nicholls, 1966; Kuffler, 1967).

Confirming the similarity with leech and amphibia, a close correlation of glial membrane potential and $[K^+]_0$ was also evident in recordings from glial cells in mammalian neocortex, optic nerve, and spinal cord (Dennis and Gerschenfeld, 1969; Ransom and Goldring, 1973a, 1973b; Lothman and Somjen, 1975; Roitbak et al., 1981) (Figure 20-3). The relatively high negative resting membrane potential, and its dependence on $[K^+]_0$, refuted the earlier contention that glial cytoplasm is in effect the "extracellular space" surrounding the neurons of the CNS.

An early report on neocortical glia by Krnjević and Schwartz (1967) indicated that glial cells have high and stable membrane potential and high input resistance, without voltage-dependent responses, action potentials, or synaptic potentials. Nor did glutamate, 5-hydroxytryptamine (5-HT), or norepinephrine administered by microiontophoresis have an effect on the membrane potential. Potassium ions released from an iontophoretic source did cause depolarization, confirming that the membrane poten-





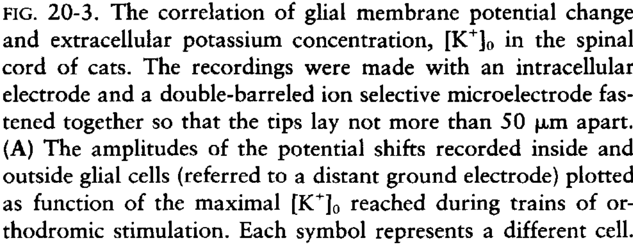


FIG. 20-3. The correlation of glial membrane potential change and extracellular potassium concentration, $[K^+]_0$ in the spinal cord of cats. The recordings were made with an intracellular electrode and a double-barreled ion selective microelectrode fastened together so that the tips lay not more than 50 μm apart. (A) The amplitudes of the potential shifts recorded inside and outside glial cells (referred to a distant ground electrode) plotted as function of the maximal $[K^+]_0$ reached during trains of orthodromic stimulation. Each symbol represents a different cell. Each cell was stimulated by several pulse trains of varying intensity and frequency applied to an afferent nerve. The vertical lines connect the simultaneously obtained data. (B) Transmembrane potential changes calculated as the sum of the extracellular and intracellular potential shifts, as function of maximal $[K^+]_0$ reached during stimulation. The line shows the Nernst function at 37.5°C, calculated assuming constancy of intracellular K^+ concentration. [From Lothman and Somjen (1975), with permission.]

tial was K^+-dependent. Large doses of γ-aminobutyric acid (GABA) caused depolarization of the unresponsive cells without changing input resistance, unlike neurons, which hyperpolarize under the influence of GABA with concomitant decrease of membrane resistance. Acetylcholine (ACh) had an action similar to GABA on some but not all "unresponsive" cells. The constancy of the input resistance was inconsistent with the opening (or closing) of ion channels, and Krnjević and Schwartz (1967) attributed the depolarization by GABA and ACh to electrogenic active uptake of these transmitter agents by the presumed glial cells.

Acknowledging conceptual precedence, Krnjević and Schwartz (1967) quoted an early essay by Lugaro (1907), who believed that one of the main functions of glia was to remove unwanted matter from cerebral interstitial spaces. This included elimination of chemical substances elaborated by nerve terminals that influence the dendrites of nerve cells. He wrote: "Protoplasmic extensions of glial cells which invariably penetrate to the vicinity of neural articulations serve to collect and to instantly break down any minimal residue of such chemical agents." With minor change of terminology, this quote could be from a review article datelined yesterday (see also Somjen, 1988).

The idea of electrogenic neurotransmitter transport by glia has recently received experimental support from Attwell's group (Brew and Attwell, 1987; Barbour et al., 1988; Sarantis and Attwell, 1990; Szatkowski et al., 1990). They found that exposure to glutamate induced a depolarizing inward current in retinal glial cells. Some, but not all, other types of neuroglia responded similarly (Schwartz and Tachibana, 1990; Wyllie et al., 1991). The current has been attributed to the influx of positively charged Na^+ ions in excess of the cotransported anionic transmitter molecules. It is activated by intracellular K^+ and inhibited by a rise of extracellular K^+ concentration ($[K^+]_0$). The uptake current is distinguished from receptor channel current by the absence of channel "noise," no change of membrane resistance, and no definable reversal potential.

THE CONTRIBUTION TO EXTRACELLULAR SUSTAINED POTENTIAL SHIFTS BY GLIAL CELLS

The origin of "slow" or "direct current," or "sustained" extracellular potential shifts, has puzzled electrophysiologists for some time. From the beginning, most investigators attributed the generation of sustained potentials either to the dendritic arbor of neurons or to glia (for review of the early literature, see Somjen, 1973). Karahashi and Goldring (1966) supplied the first experimental support for these speculations: they found that the depolarization of "idle" cells correlated with the slow negative cortical surface potentials. As mentioned earlier, at the time they too hesitated between identifying the cells as either nonspiking neuronal elements or glia. Others confirmed the basic observation (Glötzner and Grüsser, 1968; Castellucci and Goldring, 1970).

The mechanism by which glial tissue could generate extracellular potential shifts was suggested by Kuffler and associates (Kuffler and Nicholls, 1966; Kuffler, 1967; Cohen, 1970), in large part based on observations on optic nerve of amphibia. In this tissue glial cells appeared linked by gap junctions, forming a quasi-syncytial electrotonic net (see Chapter 19, this volume). Unequal depolarization of the cells so linked could generate a current flowing through and around the electrotonic net, and this current could give rise to a shift of extracellular potential that could be recorded by extracellular electrodes. These ideas were expressed in a formal model by Joyner and Somjen (1973). The model defined the relative magnitude and distribution of potential shifts around an electrotonic net as functions of the relative magnitudes of the resistances of the intercellular junctions, of the bounding membrane, and of the interstitial environment (Figures 20-4 and 20-5).

In cat spinal cord, repetitive stimulation of peripheral or dorsal root afferent fibers evokes unusually large extracellular sustained potential shifts (ΔV_0), always of negative polarity throughout the extension of the gray matter (Somjen, 1969, 1970) (Figure 20-2). The large amplitude and reproducibility of these signals facilitated their analysis (Somjen, 1970). Neither magnitude nor polarity of the sustained ΔV_0 correlated with the excitatory postsynaptic potentials (EPSPs) and inhibitory postsynaptic potentials (IPSPs) recorded from neurons. By contrast, there was a close correspondence between the depolarization of presumed glial cells and the sustained negative ΔV_0 recorded simultaneously in their immediate vicinity (Figure 20-6). This correlation held well when the recording microelectrode pair was advanced in small steps through the tissue, and a constant stimulus train was repeated at every station (Figure 20-2); and also when the recordings were made from inside and outside of a single cell while the stimulus intensity or frequency were varied (Figure 20-3). Moreover, the regression of ΔV_0 on glial depolarization remained unchanged even when both variables were reduced in amplitude by depressant drug treatment (Strittmatter and Somjen, 1973).

The introduction of ion-selective microelectrodes made the simultaneous recording of interstitial potassium concentration ($[K^+]_0$) and ΔV_0 possible.

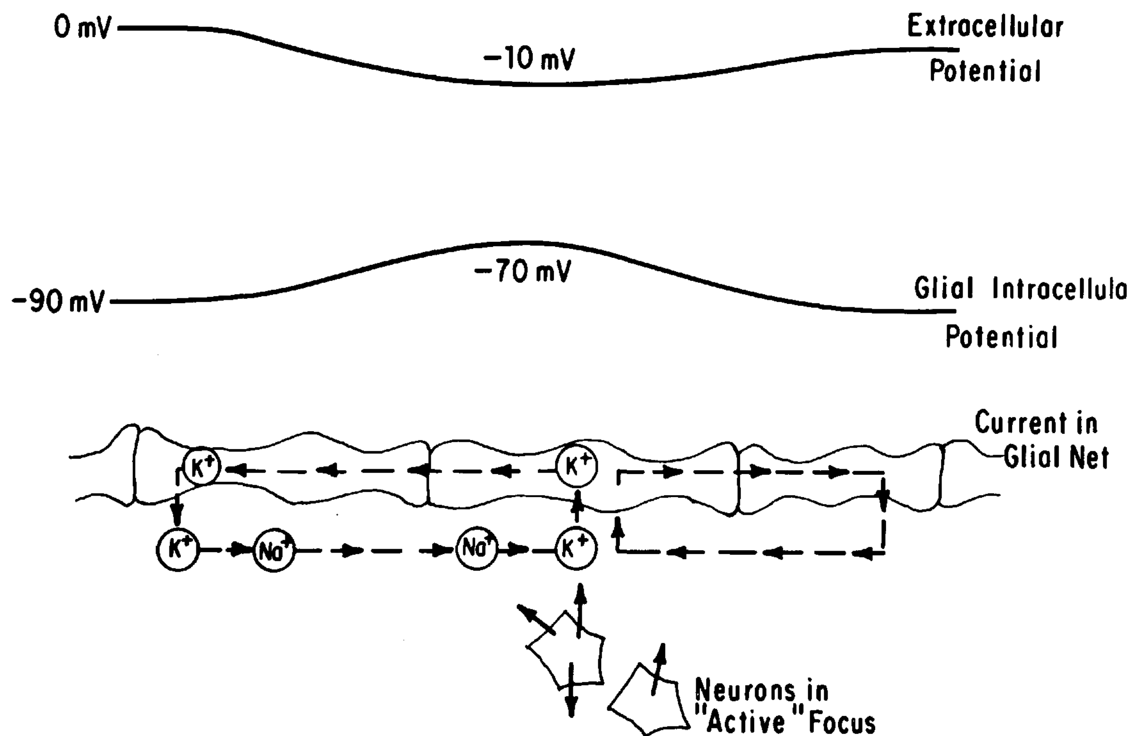

FIG. 20-4. Simplified model of the generation of extracellular ΔV_0 by the depolarization of glial cells. Near the center of the row of glial cells neurons are assumed to have released an excess of K^+ ions into the interstitial fluid. This causes depolarization of the adjacent glial cells, resulting in current flow through the gap junctions connecting the row of glial cells. The extracellular ΔV_0 corresponds to the "return" path of the current loop. Compare these hypothetical voltage profiles with the average potential profiles shown in Figure 20-2B. [From Somjen (1981), with permission.]

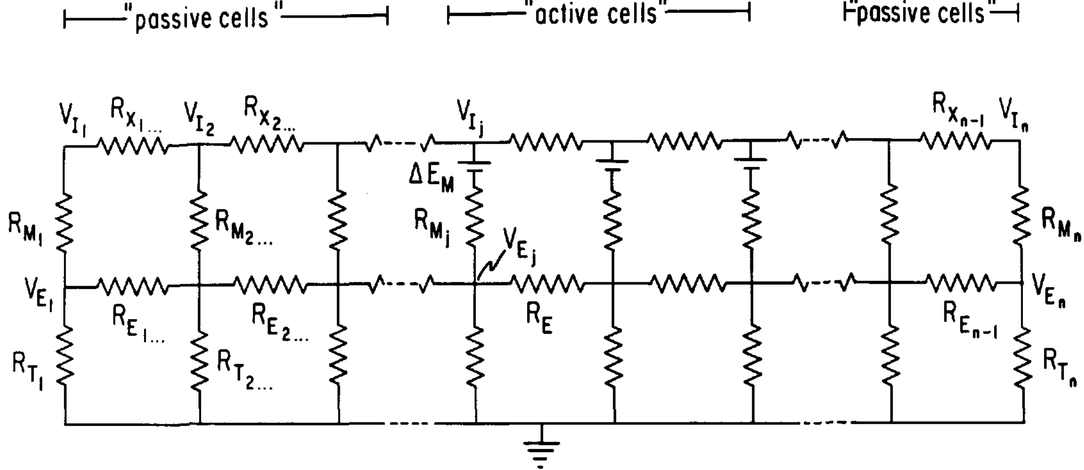
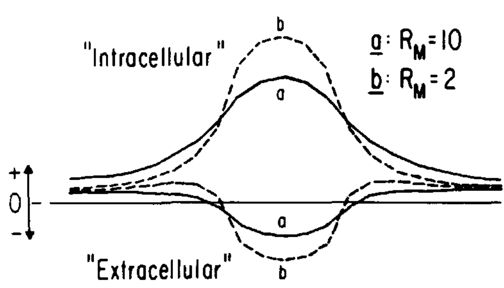
Combining such double-barreled ion selective electrodes with an intracellular electrode, the three-way correlation of sustained ΔV_0, $\Delta[K^+]_0$ and glial depolarization were confirmed. Moreover, the slope of the linear function linking the measured values of $[K^+]_0$ and glial membrane potential equaled the slope of the Nernst function calculated for a reasonably expected ratio of $[K^+]_0$:$[K^+]_i$ in mammalian glial cells (Lothman and Somjen, 1975) (Figure 20-3). This observation supported two propositions: (1) that the level of $[K^+]_0$ is the dominating influence on glial membrane potential; and (2) that the main generator of sustained ΔV_0 in cat spinal cord is the depolarization of glial cells. Indirectly, this set of observations also supported the idea that glial cells are linked by electrically patent junctions.

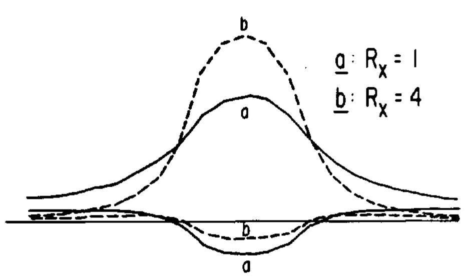
A close correlation between ΔV_0 and $\Delta[K^+]_0$ (more precisely, the logarithm of $\Delta[K^+]_0$) is a necessary but not a sufficient criterium for attributing a voltage shift to glial generation. As in spinal cord so also in cat's neocortex, the two, ΔV_0 and $\Delta[K^+]_0$, appeared correlated, but in neocortex sustained ΔV_0 responses were smaller for a given $\Delta[K^+]_0$ than in spinal cord (Lothman et al., 1975; Cordingley and Somjen, 1978; Somjen, 1978) (Figure 20-7). In other studies the depolarizing responses of glial cells also showed a relationship either to surface potentials or to interstitial ΔV_0 in many but not in all circumstances (Karahashi and Goldring, 1966; Castellucci and Goldring, 1970; Krnjević and Morris, 1972; Krnjević and Morris, 1975; Lothman et al., 1975; Cordingley and Somjen, 1978; Heinemann et al., 1979; Roitbak et al., 1981; Roitbak et al., 1987).

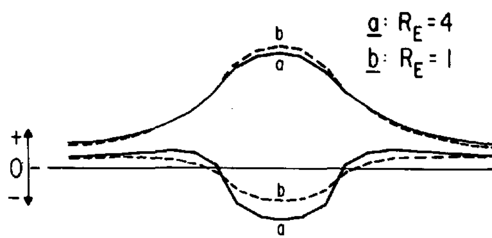
Both the smaller amplitude of ΔV_0 and its less secure correlation with $\Delta[K^+]_0$ and glial membrane potential indicate that the contribution of glia to the sustained ΔV_0 is less in cortex than in spinal cord (Figure 20-7). This could, in principle, be explained in at least three ways (Joyner and Somjen, 1973; Somjen, 1973): (1) a smaller relative size of the glial "compartment"; (2) lesser degree of electrotonic coupling, that is, fewer gap junctions or higher junctional resistances; (the higher input resistance of cortical compared to spinal glial cells (Somjen, 1975) is compatible with this explanation); and (3) lesser depolarization of cortical glia for a given $\Delta[K^+]_0$ (i.e., lesser selectivity of membrane K^+ permeability, e.g., relatively greater g_{Na^+} or "leak" conductance).

It has sometimes been argued that the low









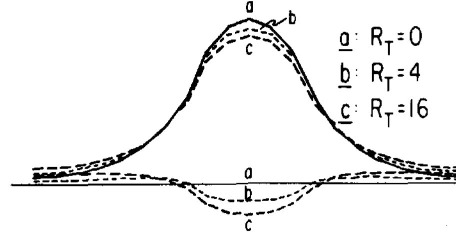


FIG. 20-5. Formal model and computer simulation of the network proposed in Figure 20-4. The upper diagram is the electric equivalent circuit; the lower four diagrams (A-D) are the numerical solutions, each for different relative values of the hypothetical resistances. "Active cells" are those assumed to be depolarized by excess $[K^+]_0$; "passive cells" those that are surrounded by normal $[K^+]_0$ but depolarized by current injected from the "active" cells. V_I, intracellular potential of glial cells; V_E, extracellular potential; R_X, coupling resistance of gap junctions connecting glial cells; R_M, membrane resistances; R_E, interstitial resistance; R_T, tissue resistance to ground; ΔE_M, "batteries" representing the depolarization caused by excess $[K^+]_0$, A-D show voltage profiles computed for varying relative magnitudes of the resistances. Compare these profiles with Figure 20-2B and Figure 20-4. [From Joyner and Somjen (1973), with permission.]

membrane resistance of glial cells precludes generation of sizeable extracellular voltages. Appropriate calculations show, however, that lowering membrane resistance (R_m) in a quasi-syncytial net does not reduce ΔV_0. The lowering of R_m does limit how far ΔV_0 spreads away from a depolarized zone, but it will actually increase the relative size of ΔV_0 within the depolarized zone. As a result, with low R_m, ΔV_0 will map in space the $\Delta[K^+]_0$ more accurately. If R_m is high, ΔV_0 spreads far outside the depolarized zone; if R_m is low,

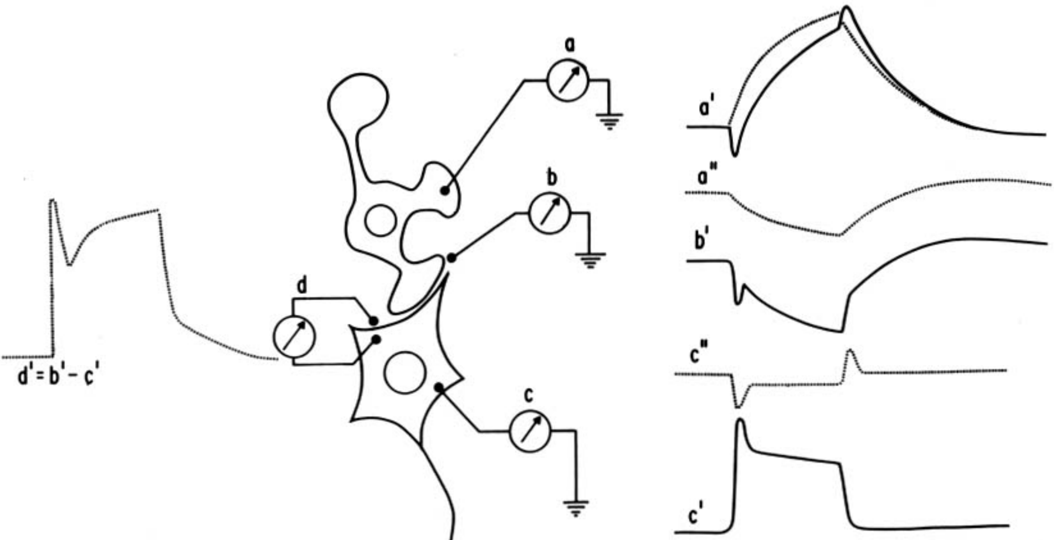

FIG. 20-6. Schematic illustration of responses of spinal cord neurons and glial cells evoked by orthodromic train stimulation, and their contribution to extracellular potential shifts, *a*, *b*, and *c* show conditions of the recordings from a glial cell, from the interstitial space, and a neuron, all referred to ground. *a'*, *b'* and *c'* show "smoothed" typical recordings from these three positions. *a"* and *c"* represent the contributions made by glia and neurons which sum to produce the extracellular ΔV_0 shown as *b'*. *d'* is the algebraic sum of neuronal intra- and extracellular potential changes, that is, the actual transmembrane potential change (EPSP) of a neuron. [From Somjen (1970), with permission.]

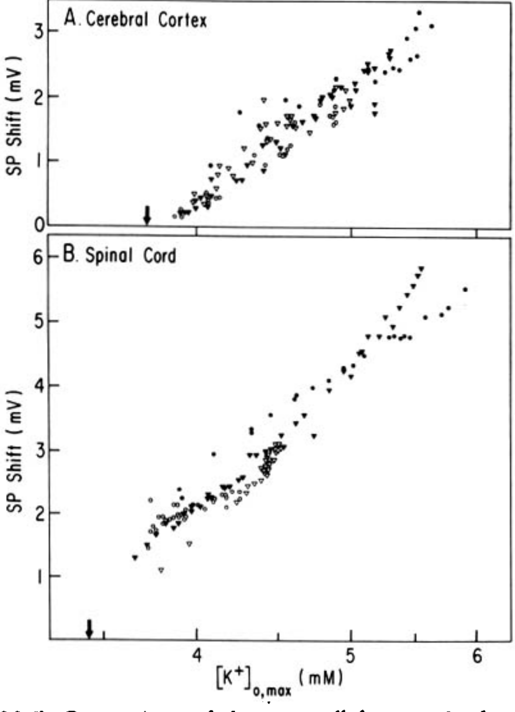

FIG. 20-7. Comparison of the extracellular sustained potential (SP or ΔV_0) shifts corresponding to varying $[K^+]_0$ levels reached during afferent train simulation in cerebral cortex and in spinal cord. Each point is the amplitude of one ΔV_0. The recordings are from a fixed site, in primary somatosensory cortex for *part A*, in the spinal dorsal horn for *part B*; responses in cortex evoked by stimulation of VPL nucleus of the thalamus; in the spinal cord by stimulation of the dorsal root. Different symbols represent series of responses obtained by varying different stimulus parameters (frequency, intensity, train duration). Note that $[K^+]_0$ is scaled logarithmically. [Experiment by G. E. Cordingley; from Somjen (1978), with permission.]

ΔV_0 remains confined to the depolarized region (Joyner and Somjen, 1973; Somjen, 1987) (Figure 20-5).

I have in this section considered the glial generation of ΔV_0 *per se*, disregarding the presumed role of glia in the "spatial buffering" of $\Delta[K^+]_0$. The role of neuroglia in regulating $[K^+]_0$ is discussed in detail in Chapter 47.

WHERE THE GLIAL CONTRIBUTION TO SUSTAINED EXTRACELLULAR POTENTIAL SHIFTS SEEMS NEGLIGIBLE

Casullo and Krnjević (1987) have recorded from glial cells in rat hippocampus. These cells could be made to depolarize by repetitive orthodromic volleys, just like their neocortical and spinal counterparts. But when the electrode was withdrawn into the interstitium, the same stimulus train usually did not evoke a detectable sustained ΔV_0. These cells did not seem to generate an extracellular current of sufficient magnitude to be detectable as a ΔV_0 by the usual recording equipment.

For entirely different reasons we have come to a similar negative conclusion concerning glia in the hippocampal formation (Somjen et al., 1985; Somjen and Giacchino, 1985; Somjen, 1993). Among the cell somata of the dentate gyrus (i.e., stratum granulosum) during repetitive orthodromic volleys, $[K^+]_0$ begins to increase at stimulus intensities that do not

evoke a sustained ΔV_0. With stronger stimulation negative ΔV_0's appear and they grow as does $\Delta[K^+]_0$, but the correlation is far less perfect than in neocortex or spinal cord. Among the dendrites of the dentate gyrus (stratum moleculare) there is no correlation between these two variables at all. In the lower range of stimulation the sustained ΔV_0 becomes increasingly negative, but then, above a certain level, it becomes smaller with increasing stimulation even though $\Delta[K^+]_0$ continues to grow. Once the stimulus trains become strong enough to provoke a seizure, in stratum moleculare a positive ΔV_0 replaces the negative ΔV_0, while $\Delta[K^+]_0$ increases all the while monotonically (Somjen and Giacchino, 1985). Current source density analysis revealed that the ΔV_0 associated with seizures in CA1 of hippocampus as well as in the dentate gyrus has a sink in the layer of cell bodies, and source among apical dendritic arbors (Wadman et al., 1992). Both, the lack of correlation between ΔV_0 and $\Delta[K^+]_0$ and the distribution of current sources and sinks, suggested that in this case the contribution of neuroglia to the extracellular sustained potential shift was negligible compared to that of neurons.

Why are hippocampal neuroglia incapable of generating sustained ΔV_0? To properly answer this question we would need to know the relative size of the glial compartment, and the density and conductance of gap junctions between glial cells. This information is currently not yet available.

PATCH-CLAMP RECORDING OF WHOLE-CELL CURRENTS FROM GLIAL CELLS

The method of tight-seal patch-clamp recording made it possible to clamp the membrane potential of whole cells as well as excised membrane patches (Hamill et al., 1981). Patch-clamp electrodes have successfully been applied to glial cells in tissue slices (Czéh et al., 1992b; Barres, 1991a; Berger et al., 1991, 1992a, 1992b; Mudrick-Donnon et al., 1992; Steinhäuser et al., 1992, 1993; Müller et al., 1993).

A pressing question of current glial research is the expression in glia *in situ* in mature CNS of the numerous membrane responses that have been discovered in glial cells in isolation and in cell cultures (Walz and MacVicar, 1988; Barres et al., 1990, 1991a, 1991b; Ransom and Sontheimer, 1992). It appears that certain of the common transmitter substances do elicit membrane ion currents in some glial cells (MacVicar et al., 1989; Berger et al., 1992b; Müller et al., 1992, 1993; Jabs et al., 1993).

In experiments not yet published in full, G. Czéh (1991, 1992a, 1992b, 1994) used patch-clamping to record from neurons and glial cells in CA1 region of rat hippocampal slices during electrically provoked seizure discharges, spreading depression (SD), and hypoxic spreading depression-like depolarization. An extracellular electrode placed in st. pyramidale very near to the patch clamp pipette served two purposes: it monitored the behavior of the surrounding neuron population; and it was connected to the "reference" input of the amplifier. Use of a reference in the tissue instead of a distant ground in the bath insured clamping of the true membrane voltage even when the extracellular potential was changing. The "diagnosis" of glial cell was made by the usual criteria of high, stable resting membrane potential and absence of synaptic or action potentials in current clamp configuration. The membrane potential of neurons and glial cells was clamped at a somewhat more negative level than the resting potential, which was determined earlier under current clamp. Membrane currents were explored at intervals by ramp voltage commands, which started with a brief hyperpolarizing step, and then depolarized the membrane along a linear trajectory by 100 mV over 200 ms. From the trajectory of the current registered during the depolarizing ramp, current-voltage (I-V) plots were then derived.

I-V plots of glial cells always yielded a straight line, indicating the absence of voltage dependent conductance change, that is, "ohmic" behavior (Figure 20-8). When the extracellular electrode registered an electrographic seizure, spreading depression, or hypoxic spreading depression-like depolarization, the holding current of the patch electrode increased, consistent with a tendency of the glial membrane to depolarize. At the same time the I-V plot derived from depolarizing ramp commands was displaced to the right, indicating depolarization, but it remained a straight line (Figure 20-8). No indication of rectification or other voltage dependent change or conductance was detected. The slope of the I-V function did usually change. The glial membrane conductance increased by 5 to 12% during electrographic seizures and by 10 to 21% during hypoxic spreading depression-like depolarization. These conductance increases were much less than those seen in neurons under similar conditions (Czéh et al., 1994). Also unlike neurons, the change in conductance of glial cells was not precisely correlated with the increase of the holding current or the shift of the reversal potential (i.e., zero current potential). In the example of Figure 20-8, the conductance is actually decreased at the moment of maximal depolarization as signaled by the increase of holding current (Czéh et al., 1991, 1992a, 1992b, 1994).

These experiments confirmed under the more rig-

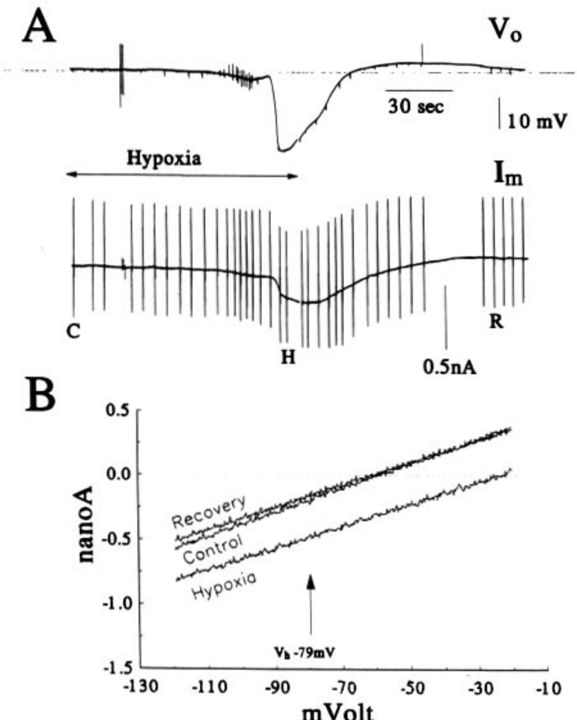

FIG. 20-8. Voltage-clamp recording from a presumed glial cell in CA1 zone of a rat hippocampal tissue slice. (A) Extracellular potential (V_0) and glial membrane holding current (I_m). The membrane potential was clamped at −79 mV. The horizontal *arrow* marked *Hypoxia* indicates the period during which N_2 replaced O_2 (with 5% CO_2) in the gas phase of the tissue chamber. The vertical lines interrupting the I_m trace result from ramp voltage commands to test current-voltage (*I-V*) functions. *C*, *H*, and *R* mark the ramp-command samples. (B) Current-voltage (I-V) plots illustrating "ohmic" resistance of glial membrane. Note right-shift of *I-V* plot during large increase of holding current, corresponding to strong negative shift of ΔV_0. Input resistances (determined from the slope of *I-V* plots): Control: 106 MΩ; Hypoxia: 116 MΩ (slightly later the input resistance decreased to 103 MΩ); Recovery: 114 MΩ. The patch pipette was filled with Cs-gluconate solution (for further technical details, see Czéh et al., 1992a). [From an experiment by G. Czéh; from Somjen et al. 1993, with permission.]

orous conditions of voltage clamp what has been observed earlier with conventional intracellular electrodes. During intense neuronal excitation, as well as under the extreme condition of spreading depression, glial cells depolarized with little or no change of membrane conductance. The most likely agent causing the depolarization is the rising $[K^+]_0$. Electrogenic transport of transmitter amino acids may also cause depolarization, but its influence should wane with rising $[K^+]_0$ (Barbour et al., 1988). The modest increase of membrane conductance may have been due to the action of transmitter agents spilling over from synaptic junctions and acting on glial receptors (MacVicar et al., 1989; Berger et al., 1992b; Clark and Mobbs, 1992; Jabs et al., 1993; Steinhäuser et al., 1993). An alternative explanation would be the opening of stretch gated channels (Kimelberg and Frangakis, 1986; Kimelberg and Kettenmann, 1990; Kimelberg et al., 1990a; Kempski et al., 1991; Puro, 1991; Bowman et al., 1992; Islas et al., 1993).

During spreading depression of Leão, glial cells undergo especially strong depolarization (Sugaya et al., 1964, 1975; Higashida et al., 1974). At the same time ΔV_0 and $\Delta[K^+]_0$ also assume unusually large magnitude. This has lead to speculation concerning a possibly leading role of glial cells in causing spreading depression. The absence of an early "active" membrane response by glia during spreading depression (Figure 20-8) weakens the suggestion of their primacy in generating this pathophysiological event (discussed in detail by Somjen et al., 1992; Herreras and Somjen, 1993).

NEWLY DISCOVERED CHANNELS, AND THEIR POSSIBLE ROLE IN SETTING GLIAL MEMBRANE POTENTIAL

The early literature has suggested two mechanisms by which glial cells could be depolarized during intense neuronal excitation: the direct effect of rising $[K^+]_0$, and electrogenic transport of neuroactive substances. Yet another potential depolarizing effect is cell swelling. At least in cultured astrocytes, a number of laboratories report depolarizing currents activated by hypotonic solutions (Kimelberg and Frangakis, 1986; Kimelberg and O'Connor, 1988; Kimelberg and Kettenmann, 1990; Kimelberg et al., 1990a; 1990b; Kempski et al., 1991; Puro, 1991; Bowman et al., 1992; Islas et al., 1993). There is evidence that glial cells do swell during neuronal excitation (Dietzel et al., 1989; Andrew and MacVicar, 1992; Osehobo et al., 1992). In these cases the swelling is assumed to be the result of the rising $[K^+]_0$ and the consequent uptake of ions and water (Ballanyi et al., 1987). The opening of swelling-activated channels could amplify the depolarization caused directly by the elevation of $[K^+]_0$.

Finally we come to the already mentioned abundance of ion channels and receptors that have recently been demonstrated. For the most part these channels were found in glial cells in culture, but some were demonstrated also in freshly isolated cells and also in tissue slices (MacVicar, 1984; Walz and MacVicar, 1988; Barres et al., 1990; Barres, 1991a; Berger et al., 1991, 1992a, 1992b; Marrero et al., 1991; Clark and Mobbs, 1992; Ransom and Sontheimer, 1992; Steinhäuser et al., 1992, 1993). Mudrick-Donnon et al. (1992) have found that the so-called stellate cells in the pars intermedia of the pituitary gland generate re-

sponses that, by all criteria, resemble $GABA_A$ and dopamine (D_2)-mediated synaptic potentials. Moreover, at least in some cells at certain stages of maturation, voltage steps also evoke "active" currents in whole cell configuration (Berger et al., 1991, 1992a; Steinhäuser et al., 1992, 1993; see Chapters 11 and 12, this volume). By and large, the older the animal from which the tissue slice is taken, and the more mature the cells in a culture, the more likely that the glial membrane responds to imposed voltage or current steps as if it was an "ohmic" resistor (Sontheimer et al., 1991; Steinhäuser et al., 1992, 1993), but the administration of transmitter agents opened ligand gated channels regardless of age (Barres, 1991a; Berger et al., 1992b; Clark and Mobbs, 1992).

CONCLUSIONS

We have found in the literature four distinct candidate mechanisms that could be responsible for the depolarization of glial cells during neuronal excitation:

1. The rise of $[K^+]_0$ in interstitial spaces during neuronal activity, which acts directly on the highly selective K^+ permeability of the glial membrane
2. The uptake of transmitter molecules by an electrogenic transport mechanism
3. The opening of stretch-activated channels during cell swelling
4. Ligand-gated channels

Although the four explanations are not mutually exclusive, it should be noted that rising $[K^+]_0$, while it is the very cause of the depolarization by the first mechanism, inhibits the second (electrogenic transport) (Barbour et al., 1988). Neither the first nor the second mechanism requires a change of membrane resistance, but the third and fourth ones do. Most writers, regardless of their adherence to one or other hypothesis, assume that the glial depolarization is subordinate to neuronal activity, and they do not assign a role in signalling or in information processing to glial cell depolarization.

The question remains, whether the inability to experimentally demonstrate the activation of ion channels in glial cells *in situ* refutes their operation in "real" brains, or whether this inability results from the inadequacy of experimental technique? Active currents have not been evoked either by depolarizing voltage or current steps. Only during intense neuronal seizure discharges and during spreading depression was there some increase of conductance of the glial membrane, but even that response remained feeble compared to that shown by neurons.

Two explanations have been offered to resolve the seemingly contradictory findings. It has been suggested that the conductance through the electrotonic coupling among glial cells shunts the membrane of individual glial cells. Changes of membrane conductance would therefore not be detected in recordings made from an individual cell, which is but a single element in an extensive randomly coupled net. Coupling among cells could indeed explain the apparently constant input resistance to voltage or current steps injected into a single cell. The same explanation is, however, not valid when the entire population of glial cells is depolarized during seizures and spreading depression. Both voltage- and ligand-gated channels of all members of the electrotonic net should be wide open under these conditions. The expected drop of resistance, spread over the surface of the entire quasi-syncytial assembly, should clearly be detectable by measurement in both current clamp and voltage clamp mode. Yet the input resistance of glial cells remains either stubbornly constant or changes only slightly in these extreme conditions.

Barres (1991b) offered another explanation for the apparently ohmic resistance, namely, that the complementary operation of inward and outward rectifying channels mutually cancel each other's effect. If this is the case, then perhaps the function of complementary inward and outward rectifying K^+-channels is to insure a high, selective, constant K^+-conductance at all membrane potential levels. Perhaps rectification is a fundamental property of specialized ion channels; perhaps it is not possible to build membrane channels that are selective for K^+, and yet conduct equally in both directions.

What then is the significance of the glial Na^+, Ca^{2+}, and Cl^- channels and of the receptors for a wide spectrum of neuroactive ligands? Speculation concerning the possible roles of these membrane constituents falls outside the scope of this chapter (see Chapter 12 for further discussion). Here we are limited to but one conclusion: the generation of glial electric signals is not among their functions.

IV Receptors

This page intentionally left blank

21 Gamma-aminobutyric acid and glutamate receptors

GABRIELA v. BLANKENFELD, KRISTIAN ENKVIST, AND HELMUT KETTENMANN

Glutamate and gamma-aminobutyric acid (GABA) are the most abundant transmitters in the central nervous system. They mediate excitation and inhibition, respectively. Released mainly at the presynaptic terminal, they can activate different types of receptors on the neuronal postsynaptic membrane. A number of recent studies, however, indicate that these specific receptors are also expressed by glial cells. In this chapter, the pharmacological and molecular properties, cellular distribution and speculations on the functional significance of glial GABA and glutamate receptors will be discussed. As will become apparent, this field of research is in a highly interesting phase: the molecular structure of the different $GABA_A$ and glutamate receptors composed of different subunits is now being elucidated. Molecular biologists have begun to learn that such receptor subunits are also present on glial cells. Thus, the picture of glial GABA and glutamate receptors is just emerging and is far from complete. Some basic facts, however, have been established: (1) glial cells can express GABA and glutamate receptors *in vitro* and *in situ* (2) there are similarities and differences between neuronal and glial receptors. These advances have not answered a key question: what is the role of glial GABA and glutamate receptors in the functioning of the brain? So far, only speculations can be offered.

METHODS USED TO STUDY GLIAL GABA AND GLUTAMATE RECEPTORS

This chapter covers several approaches to studying the properties of glial GABA and glutamate receptors. Binding studies with specific ligands indicate the presence of these receptors on glial cells. Antibodies directed against a specific domain of the receptor protein can serve to identify the individual subunits within the receptor complex in the plasma membrane and its distribution within the cell. *In situ* hybridization with specific primer sequences against mRNA coding for specific receptor subunits yields the expression pattern in different cell types and brain regions. The opening of ionotropic receptors can be directly approached with electrophysiological methods, such as the patch-clamp technique, which represents the most direct functional approach. Receptor-mediated increases in cytosolic ion concentrations or release from intracellular stores can also be monitored using optical indicators. Since activation of G protein-coupled receptors triggers a cascade of intracellular second-messenger systems, biochemical methods can also be used to study the pharmacological properties of the receptor. These studies involve investigating cell proliferation, release of substances, and activation of second-messenger pathways.

GABA RECEPTORS

Molecular Diversity

Most of the studies characterizing the biophysical and pharmacological properties of GABA and glutamate receptors in the central nervous system were performed on neurons. GABA can activate two main classes of receptors: the ionotropic $GABA_A$ and the metabotropic $GABA_B$ receptors. The $GABA_B$ receptor is coupled to a G protein. Activation of the receptor leads to an increase in K^+ conductance or a decrease in Ca^{2+} conductance of the membrane via second-messenger pathways. The molecular structure of the receptor protein is so far unknown, and there are only few reports on the expression of such receptors in glial cells: Binding of the specific $GABA_B$ receptor agonist baclofen was demonstrated in cultured astrocytes (Hösli and Hösli, 1990). The $GABA_A$ receptor contains an intrinsic ion channel mainly selective for Cl^-. The increased Cl^- conductance on receptor activation mediates inhibition in neurons. The $GABA_A$ receptor channel has a complex structure with different binding sites for barbiturates, benzodiazepines, and steroids. These substances can modulate the current flow through the receptor channel. Barbiturates and benzodiazepine agonists enhance, while inverse benzodiazepine agonists de-

crease GABA-induced responses (Sieghart, 1992). The modulation of the GABA-activated response by steroids can increase or decrease the response, depending on the type of steroid (Majewska, 1992). In analogy to the nicotinic acetylcholine receptor, the $GABA_A$ receptor is likely to be composed of five subunits. While a number of different subunits have been cloned, the composition of any type of native $GABA_A$ receptor is unknown. The α subunits (α_1 to α_6) most likely contain the benzodiazepine receptive site. In addition, a number of β (4), γ (3), and a δ subunit have been cloned (for review see Lüddens and Wisden, 1991; Sieghart, 1992).

Glial Responses to GABA Characterized in Cultured Cells

The first hints of the presence of $GABA_A$ receptors in glial cells came from studies of cultured glial cells. In these studies on primary cultures, the physiological results could be related to a certain cell type by the use of specific immunocytochemical markers (Gilbert et al., 1984; Kettenmann et al., 1984). Studies on cultured astrocytes from rat cortex described basic properties of astrocytic $GABA_A$ receptors, which revealed many similarities to neuronal $GABA_A$ receptors. The receptor contains an intrinsic Cl^- channel with similar (gross) single-channel properties as described for neuronal $GABA_A$ receptors (Bormann and Kettenmann, 1988) (see Figure 21-1B). Responses can be induced by the specific $GABA_A$ receptor agonist muscimol, and blocked by the Cl^- channel blocker picrotoxin and the antagonist bicuculline (Kettenmann and Schachner, 1985). The GABA-induced response can be enhanced by the barbiturate pentobarbital and by the benzodiazepine agonists diazepam or flunitrazepam. Steroid hormones can act as positive or negative modulators of the GABA-induced response (Chvatal and Kettenmann, 1991) (see Figure 21-1D). The dose-response curve revealed the presence of two allosteric GABA binding sites on the receptor complex (Bormann and Kettenmann, 1988) (see Figure 21-1C).

These studies in astrocytes, however, also demonstrated differences in comparison to neuronal $GABA_A$ receptors: the inverse benzodiazepine agonists such as the β-carboline DMCM enhanced the response in astrocytes in contrast to its inhibitory effect in neurons (Backus et al., 1988). The subunit composition of $GABA_A$ receptors in cultured astrocytes was analyzed in a study by Bovolin et al. (1992) with *in situ* hybridization techniques. The expression pattern of 14 subunits was studied in cultured granule cells as compared to cerebellar astrocytes. The total amount of mRNA was found to be two times higher in granule cells than in astrocytes. While mRNAs coding for the α_6 and the γ_2 subunit were not detected, mRNA for all other 12 subunits was found in the astrocytes. Prominent expression of the α_1, α_2, and γ_1 was found, the latter subunit could mediate the different DMCM sensitivity seen in patch-clamp experiments.

In cells of the oligodendrocyte lineage the inverse benzodiazepine agonist DMCM acted as in neurons, in contrast to the responses in astrocytes. However, the dose-response curve revealed no allosteric interaction between binding sites as described for astrocytic and neuronal $GABA_A$ receptors (Blankenfeld et al., 1991). These studies indicate that cultured glial cells express receptors with different pharmacological properties.

GABA Receptor Activation Depolarizes Glial Cells

In most adult neurons, the activation of $GABA_A$ receptors leads to a hyperpolarization of the membrane due to an influx of Cl^- into the cell. Some immature neurons, however, are depolarized by GABA, which is thought to act as an excitatory transmitter in early postnatal development (Cherubini et al., 1991). Independent of developmental stage or brain region, astrocytes and oligodendrocytes were always found to be depolarized by GABA. This is due to a different Cl^- distribution in neurons and glial cells. In glial cells the intracellular Cl^- concentration is increased far above the passive distribution, leading to an efflux of Cl^- as determined with ion-selective microelectrodes (Kettenmann et al., 1987; Hoppe and Kettenmann, 1989) (see Figure 21-1A). In oligodendrocytes, the Cl^- inward transport is primarily due to the activity of a bumetanide-sensitive $Na^+/K^+/Cl^-$ transport system. The mechanism of Cl^- transport across the astrocytic membrane additionally involves $Na^+/K^+/2Cl^-$ cotransport and Cl^-/HCO_3^- exchange (Kettenmann, 1990; Kimelberg, 1990). This difference in ion flux direction between adult neurons and glial cells could be of functional importance (as discussed below).

In glial precursor cells it was found that the GABA-induced depolarization activates voltage-gated Ca^{2+} channels (Kirchhoff and Kettenmann, 1992) (see Figure 21-2). The resulting increase of cytosolic Ca^{2+} could be a signal leading to physiological changes in glial precursor cells. In more mature oligodendrocytes, the depolarization is too small to activate the Ca^{2+} channels (see Figure 21-2).

New Insights from Studies on Glial Cells In Situ

The cell culture studies described above demonstrated that glial cells have the capacity to express

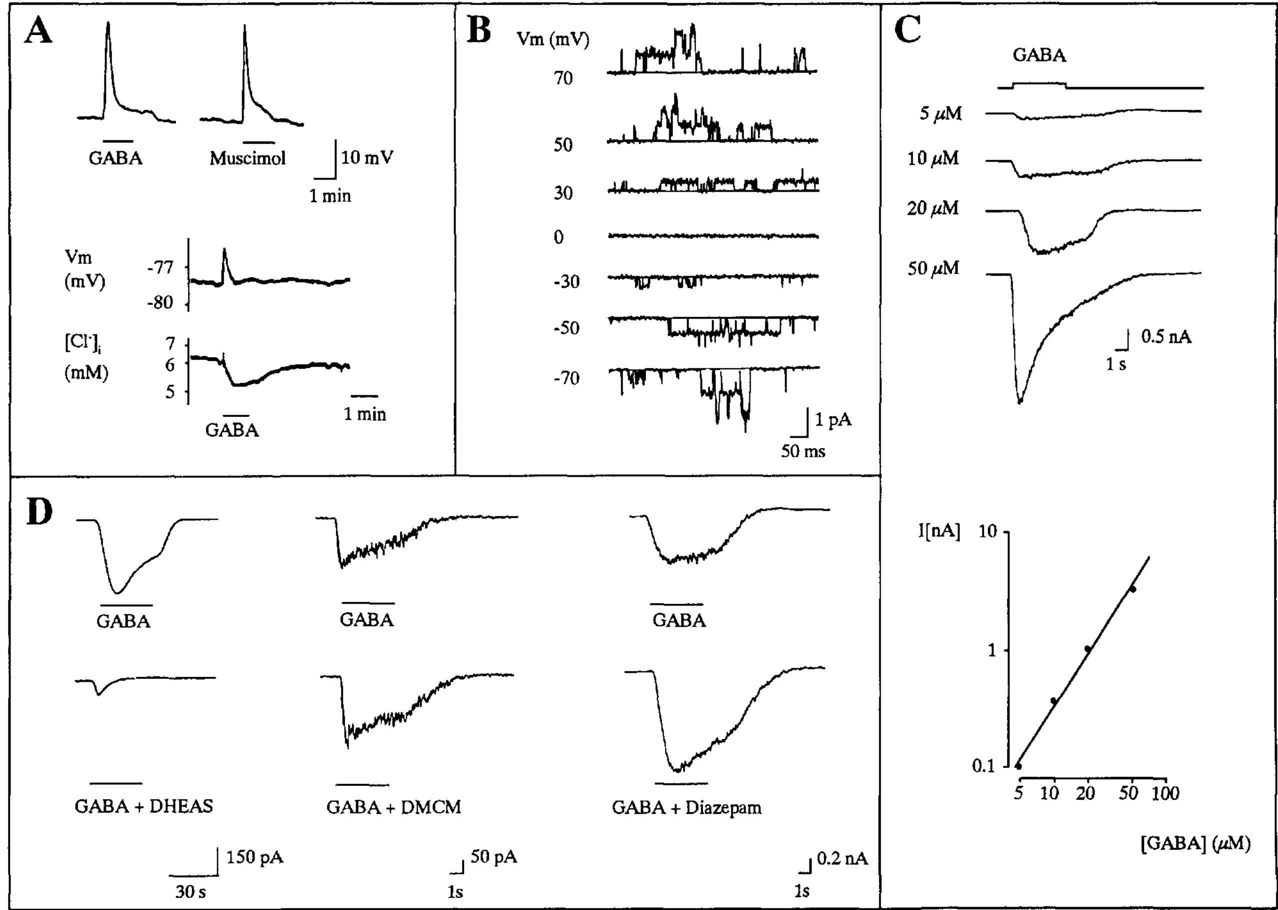

FIG. 21-1. Properties of $GABA_A$ receptors in cultured astrocytes. **(A)** Effect of 1 mM GABA and muscimol on the membrane potential of a cultured cortical astrocyte, as recorded with intracellular microelectrodes. Muscimol induced a similar depolarization as GABA, indicating the activation of $GABA_A$ receptors [*upper traces*: from Kettenmann and Schachner (1987), with permission.] Using an ion-selective recording technique, the intracellular Cl^- concentration was determined while simultaneously monitoring the membrane potential, in a cultured oligodendrocyte from the spinal cord [*lower trace*: from Hoppe et al. (1989), with permission.] The traces demonstrate that the depolarization is caused by Cl^- efflux. **(B)** Single-channel currents activated by GABA were recorded with the patch-clamp technique in the outside-out configuration from a cultured astrocyte at different membrane potentials. With symmetrical Cl^- and uneven Na^+ K^+ distribution, single-channel currents reversed polarity at about 0 mV, the Cl^- equilibrium potential. The single-channel conductance calculated from the resulting voltage-curve was 29 pS. [From Bormann and Kettenmann (1988), with permission.] **(C)** Whole-cell current recordings from a cultured astrocyte in response to increasing concentrations of GABA (*upper trace*). In the graph below, inward currents are plotted on a double-logarithmic scale versus the GABA concentration. The slope of the dose-response relationship of the GABA-induced currents is about 1.6, indicating allosteric interactions between two ligand binding sites. [From Bormann and Kettenmann (1988), with permission.] **(D)** Modulation of $GABA_A$ receptor channels in cultured astrocytes by agonists to the steroid or benzodiazepine binding site. The steroid DHEAS decreased the GABA-activated currents. [From Chvatal et al. (1991), with permission.] DMCM, and diazepam, an inverse and full agonist, respectively, both increased the GABA-induced current response. [From Bormann and Kettenmann (1988), with permission.]

GABA and glutamate receptors. No information was available about the distribution of GABA receptors in glial cells in respect to brain area and cellular microenvironment. This question can now be addressed owing to recent advances in physiological and molecular biological techniques. With the application of the patch-clamp method to thin-slices, glial cells can be studied in an intact environment. In the following preparations, glial GABA receptors were investigated with this technique: in astrocytes of the retina (Malchow et al., 1989; Clark and Mobbs, 1992) and hippocampus (Steinhäuser et al., 1994), in glial precursor cells and oligodendroctyes of the corpus callosum (Berger et al., 1992), and in Bergmann glial cells of the cerebellum (Müller et al., 1993a). Antibodies specific for subtypes of $GABA_A$ receptor subunits gave some information about the subunit composition of glial GABA receptors. In particular, studies on two types of glial cells have increased our knowledge about the properties of

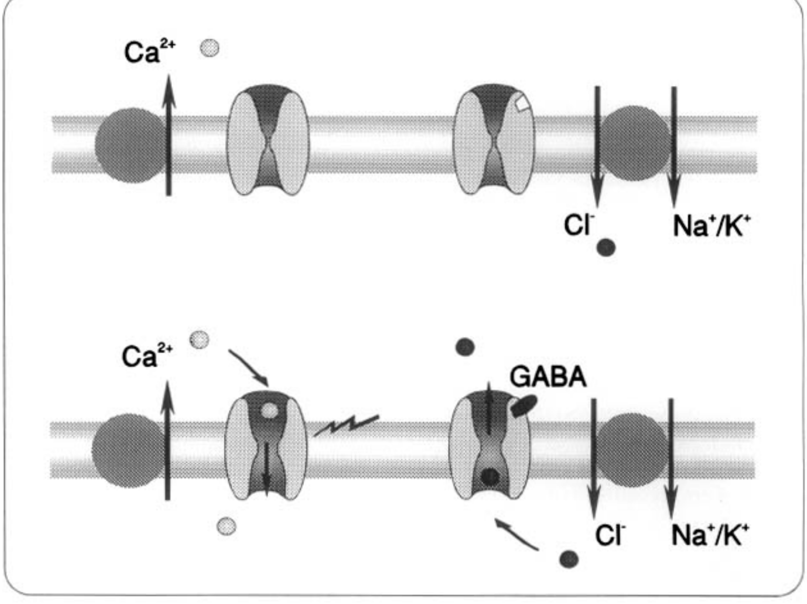

FIG. 21-2. Developmental changes in GABA-induced Ca^{2+} movements. The development of oligodendrocytes from their precursor cells is accompanied by morphological changes and a change in the antigenic phenotype (*upper diagram*). A2B5-positive, immature precursor cells express $GABA_A$ receptors and two types of voltage-activated Ca^{2+} channels. The activation of the GABA receptor leads to an influx of Ca^{2+} through these channels, as shown in the *lower trace* [from Kirchhoff and Kettenmann (1992), with permission.] Whereas O4-positive precursor cells and O1-positive oligodendrocytes have no voltage-activated Ca^{2+} channels, the O10 positive oligodendrocyte express Ca^{2+} channels, but only a few $GABA_A$ receptors. The activation of these $GABA_A$ receptors is not sufficient to activate the Ca^{2+} channels and trigger a Ca^{2+} flux. The following mechanisms (most likely) link $GABA_A$ receptor activation and activation of voltage-gated Ca^{2+} channels: the internal Cl^- in oligodendrocytes is elevated above the passive distribution, by the action of a bumetanide-sensitive $Cl^-/Na^+/K^+$ cotransporter. $GABA_A$ receptor activation opens the Cl^- channel, leading to an efflux of Cl^- and a resulting depolarization of the membrane. The depolarization activates voltage-gated Ca^{2+} channels, and triggers the flux of Ca^{2+} into the cell.

glial GABA receptors *in situ*; Bergmann glial cells, and oligodendrocytes.

In an *in situ* hybridization study on Bergmann glial cells, mRNA coding for the α_2 and the γ_1 subunit was found (Wisden et al., 1989). Studies with monoclonal antibodies against the different receptor subunits showed the α_2 and the δ subunit to be part of the receptor complex (Müller et al., 1994). The widespread γ_2 subunit, which confers benzodiazepine sensitivity to a $GABA_A$ receptor complex, could not be demonstrated using *in situ* hybridization (Wisden et al., 1989) or immunohistochemistry (Müller et al., 1994). Indeed, electrophysiological studies verified that Bergmann glial cells were unresponsive to benzodiazepines. Moreover, activation of $GABA_A$ receptors not only opens Cl^- channels, but also transiently induces a blocking of K^+ channels. The molecular mechanisms leading to the reduction of the K^+ conductance is not understood (Müller et al., 1994).

Glial cell processes in white matter tracts of adult cats could be stained with polyclonal antibodies

against the β_1 subunit. No immunoreactivity was found on microglial or oligodendroglial cell bodies (Gu et al., 1992). In thin slices of the corpus callosum the expression of $GABA_A$ receptors on glioblasts and oligodendrocytes could be verified with electrophysiological methods (Berger et al., 1992).

Developmental Regulation

Tissue culture studies have indicated a developmental regulation of $GABA_A$ receptor expression in the oligodendrocyte lineage. The density of $GABA_A$ receptors on glial precursor cells was about 100 times higher, as compared to oligdendrocytes (Blankenfeld et al., 1991). A similar tendency was also observed for glioblasts and oligodendrocyte in the corpus callosum (Berger et al., 1992). While the receptor expression in cells of the oligodendrocyte lineage decreased continuously during development, $GABA_A$ receptor expression was transient in Bergmann glial cells: it was maximal during the time period of granule cell migration along the Bergmann glial processes to the inner granule cell layer. At that developmental period, the Purkinje cells also form contacts with the parallel fibers. In the adult animal, Bergmann glial cells ensheath the dendrites of the Purkinje cells (Müller et al., 1994). This precise developmental timing of the expression of the receptor leads to the speculation that glial $GABA_A$ receptors have a synchronizing function during these developmental events.

GLUTAMATE RECEPTORS

The glutamate receptors form a family of receptors with different properties. Ionotropic NMDA and AMPA-kainate receptors, and the metabotropic glutamate receptors are composed of a number of subunits that introduce different properties to the receptor complex.

Activation of the ionotropic AMPA-kainate receptor leads to the opening of a cation channel which depolarizes the membrane. In neurons this event mediates excitation. Among the ionotropic receptor class, a number of subunits that make up the functional receptor, either as a homomer or heteromer, have been cloned (for review see Nakanishi, 1992; Sommer and Seeburg, 1992). The GluR2 subunit appears to be particularly important for the properties of the receptor channel. If this subunit is present, the receptors have a near-linear current-voltage relationship, and low Ca^{2+} permeability. In the absence of the GluR2 subunit the channels display rectification and are significantly permeable to Ca^{2+} in addition to the Na^+/K^+ permeability.

Metabotropic glutamate receptors resemble other G protein-coupled receptors in the plasma membrane, with an extracellular NH_3 terminal and seven transmembrane segments. Like the ionotropic receptors, they can be divided into subgroups (for review see Nakanishi, 1992). Functionally, metabotropic glutamate receptors are coupled to breakdown of inositol phospholipids, leading to activation of PKC by diacylglycerol, and mobilization of Ca^{2+} from intracellular stores by IP_3. Subtypes coupled to a decrease in cAMP and cGMP levels have also been reported.

Ionotropic Glutamate Receptors in Cultured Glial Cells

As with the $GABA_A$ receptor, our first knowledge of the glial glutamate receptor came from studies of cultured glial cells (see Figure 21-3). Using electrophysiological techniques Bowman and Kimelberg (1984) and Kettenmann et al. (1984) demonstrated depolarizations induced by glutamate in cultured astroglia. The agonists kainate and quisqualate, but not NMDA, mimicked the glutamate response hinting to the presence of AMPA-kainate receptors, as demonstrated by electrophysiological methods (Bowman and Kimelberg, 1984; Kettenmann et al., 1984; Kettenmann and Schachner, 1985) or by monitoring [^{3}H]GABA release (Gallo et al., 1989). Receptor activation leads to an opening of a cationic pore like in neurons (Sontheimer et al., 1988), with concomitant influx of Ca^{2+} from the extracellular space (Enkvist et al., 1989). Glutamate receptors have been demonstrated in a number of different cell culture systems, including type I and II astrocytes and oligodendrocytes (for review see Blankenfeld and Kettenmann, 1992).

The glutamate receptor in cerebellar process-bearing astroglia has been characterized at the single-channel level and possesses at least five subconductance levels, ranging from 6 to 47 pS, unlike kainate receptors in neurons (Usowicz et al., 1989). In some culture systems, glutamate receptor currents have been recorded only after at least 1 week in culture, indicating that environmental factors can control their expression (Wyllie et al., 1991). The presence of a kainate binding protein, presumed to be part to a kainate receptor, was first demonstrated by Gregor et al. (1989) in cultured chick Bergmann glia.

Metabotropic Glutamate Receptors in Cultured Glial Cells

Evidence for the expression of metabotropic glutamate receptors in cortical astroglial cells was first presented by Pearce et al. (1986). They demon-

strated increases in both the breakdown of inositol phospholipids and $^{45}Ca^{2+}$ efflux upon stimulation with glutamate receptor agonists. The efficacy was in the order quisqualate ≥ glutamate > kainate >> NMDA, which is the expected pharmacology of the metabotropic quisqualate receptor subtypes mGluR1 and R5. This finding was substantiated by Enkvist et al. (1989) with the use of the optical indicator fura-2, demonstrating both Ca^{2+} influx and Ca^{2+} release from intracellular stores in cultured cortical astroglia in response to glutamate and quisqualate (see Figure 21-3). Glutamate-induced oscillations in cytosolic Ca^{2+} in single-cultured astroglia were described by Glaum et al. (1990) and Jensen and Chiu (1990) using optical indicators. The increases in cytosolic Ca^{2+} triggered by activation of the metabotropic receptor are thought to be involved in generating Ca^{2+} waves spreading through an astrocytic syncytium (Cornell-Bell et al., 1990a; see Chapter 10, this volume).

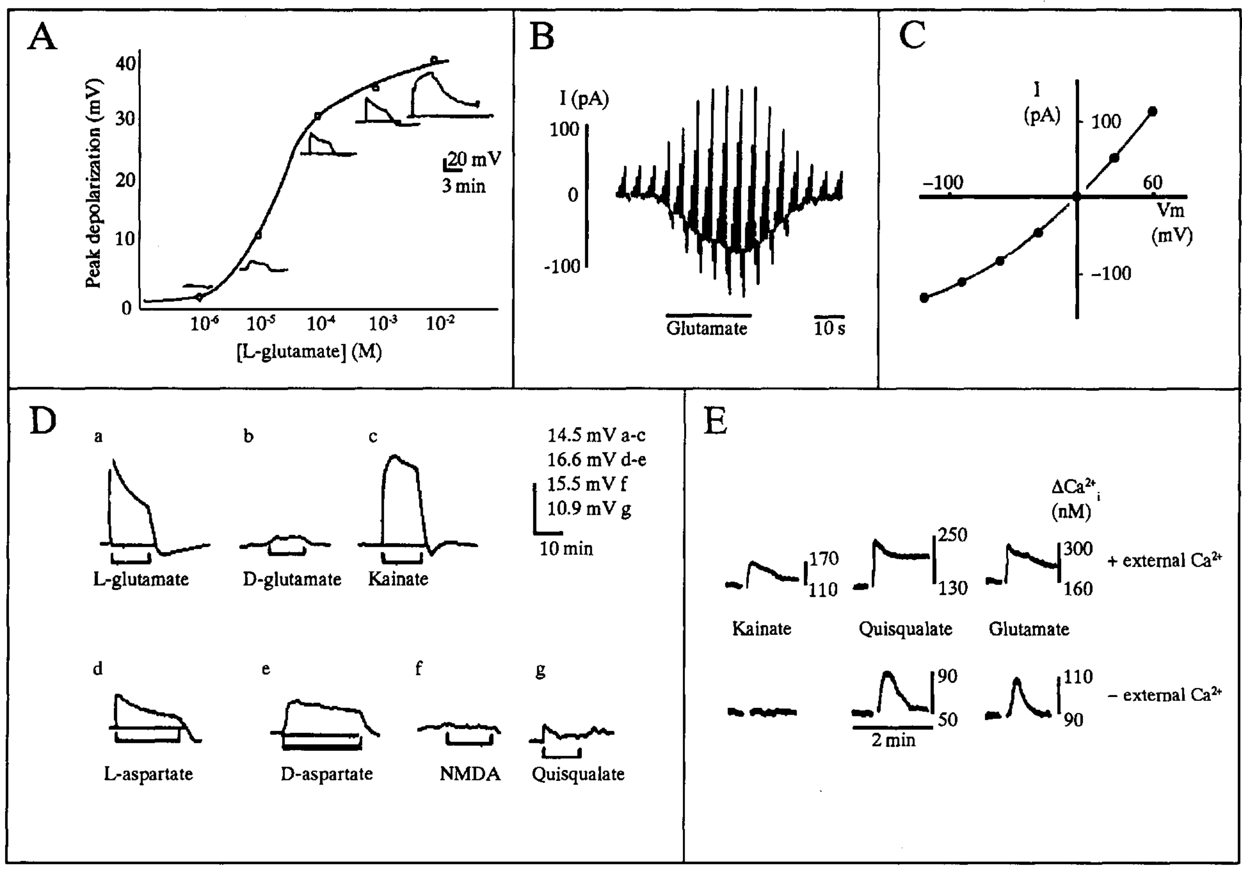

FIG. 21-3. Properties of the glutamate receptor in cultured astrocytes. **(A)** Depolarizing responses to increasing concentrations of L-glutamate. Initial peak depolarizations are plotted versus agonist concentration. The dose-response curve was obtained from a single-cultured astroglial cell, using an intracellular microelectrode measuring the membrane potential, and applying increasing concentrations of agonist. The *insets* show responses to the indicated concentrations. [From Bowman and Kimelberg (1984), with permission.] **(B)** Patch-clamp recordings from a single astroglial cell. The membrane current was measured while briefly clamping the cell's membrane potential to different values, from a resting potential of −60 mV to −120, −90, −30, 0, 30, and 60 mV. The duration of the voltage pulse was 200 ms, with a 1-second interval between pulses. The application of glutamate in the bathing medium significantly increased membrane currents, indicating the opening of an ion channel. [From Sontheimer et al. (1988), with permission.] **(C)** Current voltage curve obtained from the measurements in Figure B. The measured current at each of the voltage steps under control conditions is subtracted from that measured after the application of glutamate. The current voltage curve reverses at a membrane potential of 0 mV as expected for a cationic conductance and is similar to neuronal AMPA-kainate receptors. [From Sontheimer et al. (1988), with permission.] (D) Pharmacology of astroglial responses to excitatory amino acids. The membrane potential of cultured astroglial cells was measured with an intracellular microelectrode. All applications are 10^{-4} M. This pharmacological profile identifies the receptor as an AMPA-kainate type glutamate receptor. [From Bowman and Kimelberg (1984), with permission.] (E) Increases in intracellular Ca^{2+} measured with the optical indicator fura-2. All applications are 5×10^{-4} M. In the absence of extracellular Ca^{2+}, quisqualate and glutamate induce a transient increase in intracellular Ca^{2+}, suggesting release from intracellular stores. Kainate only causes a Ca^{2+} increase in Ca^{2+}-containing extracellular buffer, indicating influx of this ion. This pattern of Ca^{2+} responses is expected in cells expressing both metabotropic and ionotropic receptors. [From Enkvist et al. (1989), with permission.]

Glutamate Receptors in Intact Tissue

The presence of glutamate receptors was recently demonstrated in acutely isolated slices, using both electrophysiology and *in situ* hybridization. With that approach the presence of glutamate receptors was verified in cells of the oligodendrocyte lineage in the corpus callosum (Berger et al., 1992), Bergmann glial cells from the cerebellum (Müller et al., 1992), glial cells from the hippocampus (Steinhäuser et al., 1994) and astrocytes from the rabbit retina (Clark and Mobbs, 1992). Patch-clamp studies in Bergmann glial cells revealed that this ionotropic glutamate receptor channel is Ca^{2+}-permeable and has a nonlinear current voltage relationship (see Figure 21-4). *In situ* hybridization showed the expression of the GluR1 and GluR4 subunits, but not of the GluR2 in these cells (Monyer et al., 1991). Recombinant receptors lacking the GluR2 subunit displayed the same properties as those in the Bergmann glial cells in thin slices and in cultured fusiform glial cells from the cerebellum (Burnashev et al., 1992). The study on Bergmann glia in intact slices also revealed that glutamate receptor activation is accompanied by a transient reduction of the resting K^+ conductance, most likely mediated by the influx of Ca^{2+} (Müller et al., 1992). A similar effect on the K^+ conductance was also observed in glial cells from the hippocampus (Steinhäuser et al., 1994). The physiological implications of this link

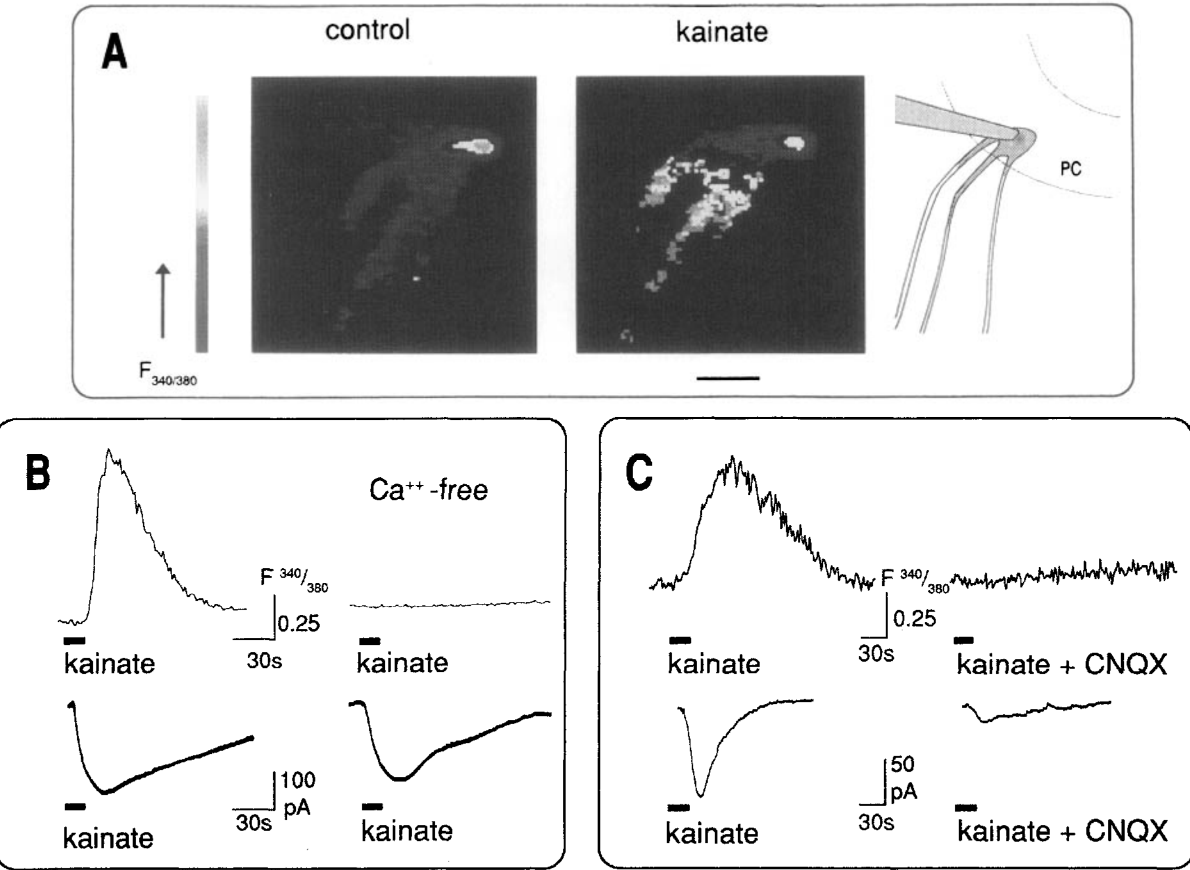

FIG. 21-4. Responses to kainate in Bergmann glial cells in an acutely isolated cerebellar slice. (A) A cell was filled with the calcium indicator dye fura-2 by loading from the patch-clamp pipette, and intracellular Ca^{2+} concentration was monitored on a video-based imaging system. The gray scale to the *left* of the pictures represents intracellular Ca^{2+} levels. The diagram on the *right* shows the cell with the pipette still attached to the soma. Three processes can be distinguished. The bar denotes 20 μm. The images illustrate the increase in intracellular calcium seen during the application of 1 mM kainate. (B) Effects of low extracellular calcium concentration. The *upper traces* show the fluorescence ratio at 340/380 nm excitation of fura-2. An upward deflection of the curve denotes an increase in intracellular calcium. The *lower traces* show simultaneous recording of membrane currents using whole cell voltage clamp. A downward deflection of the curve indicates an inward current. In the calcium-free solution no increase in intracellular calcium is seen, while the kainate-induced currents remain unaffected. This suggests that the calcium response is due to the influx of this ion from the extracellular space. (C) Responses to kainate, both intracellular calcium and membrane currents, are blocked by the ionotropic glutamate receptor antagonist CNQX. [From Müller et al. (1992), with permission.]

between glutamate receptor activation and K^+ channel activity are not understood, but it will clearly influence the K^+ buffering properties of the glial cell (see Chapter 10, this volume).

Responses to NMDA

Cultured glial cells have not been reported to respond to NMDA. However, responses to NMDA have been recorded in Bergmann glial cells in cerebellar slices and glial cells of the hippocampal slice (Steinhäuser et al., 1994; Müller et al., 1993). The current response is linked to an increase in membrane conductance associated with an increase in current noise (Müller et al., 1993). Surprisingly, these responses did not lead to a change in cytosolic Ca^{2+} and were not affected by the presence of Mg^{2+} or glycine as expected from the behavior of the neuronal NMDA receptors. So far, the molecular properties of glial NMDA receptors have not been described.

FUNCTIONAL CONSEQUENCES OF GABA AND GLUTAMATE RECEPTOR ACTIVATION

Recently, we have learned that glial cells have the capability to express distinct receptors for GABA and glutamate, and we have described their basic biophysical and pharmacological properties. However, the functional importance of these receptors on glia remains unknown. In the following sections, some data on physiological responses in glial cells to GABA and glutamate agonists are presented together with some speculations about possible functions.

GABA Receptors May Be Involved in Cl^- Homeostasis

In neurons, activation of $GABA_A$ receptors commonly leads to an influx of Cl^- into the cell, resulting in hyperpolarizing inhibitory postsynaptic potentials (ipsp), in contrast to glial cells where the membrane is depolarized. Since astrocytic processes are found in close vicinity to synapses, the efflux of Cl^- from adjacent astrocytic processes through GABA-activated Cl^- channels could serve to maintain a constant extracellular Cl^- at the synaptic cleft (Bormann and Kettenmann, 1988; MacVicar et al., 1989). The astrocytic $GABA_A$ receptor may thus serve to buffer extracellular Cl^- levels at synaptic regions. This would comprise an additional function of astrocytes, that of providing Cl^- homeostasis, besides their presumed involvement in the regulation of extracellular K^+.

Astrocytic Swelling by Glutamate Receptor Activation

Glutamate application causes astrocytes to swell. Since astrocytic swelling is an important event after head trauma leading to neurological impairment (see Chapter 10, this volume), the control of astrocytic volume is of high clinical importance. Smaller glial volume changes could also influence the volume of the extracellular space around neurons and thus modulate neuronal activity. Increases in astrocytic cell volume in response to glutamate was reported by several investigators (for review see Kimelberg, 1992). The effect of kainate on astrocytic swelling makes it likely that AMPA-kainate receptors are involved since kainate is not used as substrate for the glutamate uptake carrier (Kimelberg et al., 1989). Chan et al. (1990) observed that glutamate, aspartate, and quisqualate, but not kainate application resulted in the swelling of cortical astroglia. Interestingly, the swelling was antagonized by the NMDA receptor antagonists ketamine and MK-801 (Chan and Chu, 1989; Chan et al. 1990), which clearly demonstrates that the effect of glutamate on glial cells is more complex than expected from the pharmacology of the electrical and Ca^{2+} responses.

Control of Proliferation by Glutamate

Glutamate has also been shown to affect the proliferation of cortical astroglia as determined by [^{3}H]thymidine incorporation (Condorelli et al., 1989; Nicoletti et al., 1990), without affecting the overall viability of the cells. The pharmacology suggested the involvement of a metabotropic glutamate receptor. This was further supported by the finding that excitatory amino acids reduced the thymidine incorporation with a similar pharmacological profile as their effect on phosphoinositide lipid hydrolysis (Nicoletti et al., 1990).

Synaptic Activity Could Influence Glial Cells in the Vicinity via Glial Receptor Activation

In cultured hippocampal astroglia, Cornell-Bell et al. (1990b) demonstrated that application of glutamate induced a rapid formation of filopodia. The pharmacology of this response was compatible with the activation of non-NMDA receptors, since it could be mimicked by both quisqualate and kainate, but not

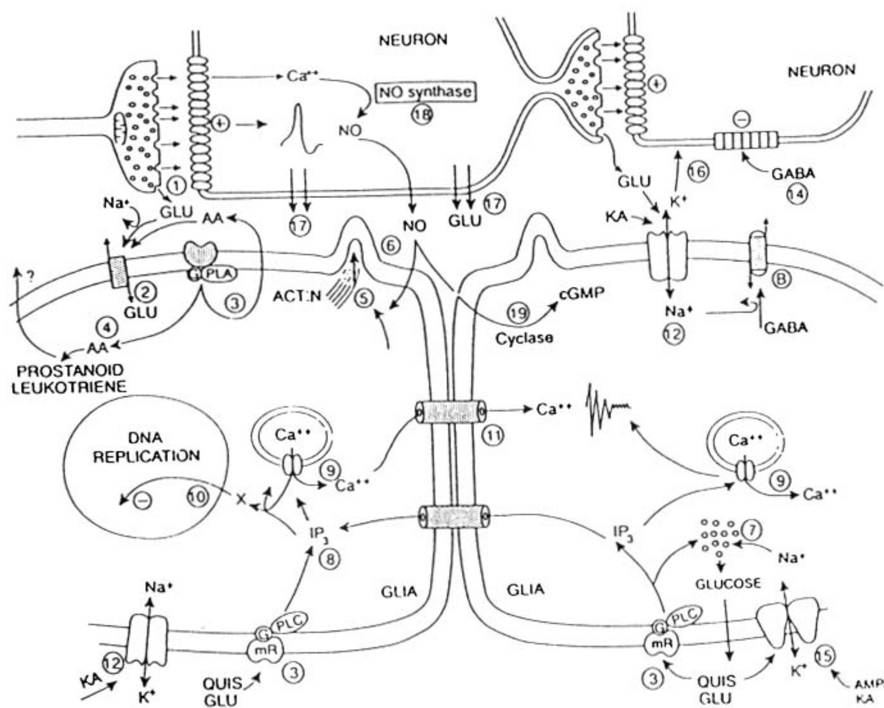

FIG. 21-5. Scheme of glutamatergic signaling pathways in neurons and glia. (*1*) Glutamate (GLU) release and postsynaptic excitation. (*3*) Activation of the GLU metabotropic receptor to reduce (*4*) AA, (*5*) actin reorganization, (*6*) filopodia formation, (*7*) glycogenolysis, (*8*) IP_3 formation, (*9*) calcium release, and (*10*) inhibition of replication. (*11*) Permeation through gap junctions and calcium waves. (*12*) Activation of ionotropic receptors by GLU, influx of Na^+ and efflux of K^+. (*14*) Extrasynaptic inhibition by GABA. (*15*) Activation of AMPA receptors by GLU. (*16*) K^+ induced depolarization. (*17*) Axonal release of GLU. (*18*) NMDA receptor activation, calcium entry and stimulation of NO synthase. (*19*) Diffusion of NO from the neuronal compartment to the glial compartment and stimulation of guanylate cyclase and cGMP formation. [From Teichberg (1991), with permission.]

by NMDA. The authors concluded that the filopodia formation is mediated by inositol phospholipid hydrolysis, resulting in a reorganization of the cytoskeleton.

It can also be speculated that *in vivo* synaptic release of these neurotransmitters could activate transmitter receptors on glial cells and trigger extension of glial processes. The presence of glial processes around a synapse could be important for synaptic stability. Survival or annihilation could be mediated by glial activity triggered by the synapse itself. The concept for such a neuron-glia interaction is strengthened by the observation that the transplantation of astrocytes into the adult cat visual cortex reestablished ocular dominance plasticity (Müller and Best, 1989). Neuron-glia interactions at synaptic regions could thus be important for long-term modification of signal transduction, resulting in complex functions such as "memory." The involvement of glial transmitter receptors in such a neuron-glia interaction could even involve complex, interactive processes. For instance, nitric oxide released from neurons upon NMDA receptor stimulation could activate glial guanylate cyclase (Garthwaite, 1991). GABA is released from glial cells on glutamate receptor stimulation (Gallo et al., 1989) and could inhibit neuronal signaling. These possible, complex interactions are summarized in the Figure 21-5 diagram by Teichberg et al. (1991).

22 Acetylcholine and serotonin receptor activation

WOLFGANG WALZ

Progress in studying the roles of acetylcholine and serotonin in neuronal-glial interactions has not been as dramatic as in the cases of glutamate and GABA (see Chapter 21, this volume). Indeed, the best evidence for such interactions comes from invertebrate nervous systems rather than mammalian preparations. The reason may be that both acetylcholine and serotonin are less widely used in synaptic transmission than glutamate and GABA. In mammals, cholinergic neurons are localized in discrete nuclei in lower regions of the brain, sending their axons throughout the neocortex. Most serotonergic neurons are located in the raphe nuclei, but some other areas contain them. However, there is an extensive, patternless innervation of the cerebral cortex. Interestingly, most of the serotonergic varicosities are characterized by nonsynaptic contacts (Ridet et al., 1993). The proportion of astrocytes around these varicosities is quite high. The distance between these varicosities and astrocytes is about twice as large as that between synaptic vesicles in serotonergic synapes and astrocytes. The possibility that serotonin may not only be released by synapses but also by varicosities opens interesting possibilities of interactions between these serotonergic pathways and neighboring astrocytes.

ACETYLCHOLINE

Effects of Acetylcholine on Invertebrate Glial Cells

Neuropile Glial Cells of the Leech. Ballanyi and Schlue (1989) investigated the effect of acetylcholine receptor activation on the physiological properties of neuropile glial cells in the leech central nervous system. Application of acetylcholine elicits a small depolarization. The amplitude can be increased severalfold after exposure to acetylcholine esterase blockers. In the presence of these blockers the concentration threshold for acetylcholine was below 5 μM. Carbachol is less potent than acetylcholine (in the presence of these inhibitors), whereas nicotine is more potent than acetylcholine. The peak depolarizations reached 40 mV. A pharmacological profile of the response revealed a nicotinic receptor subtype (Ballanyi and Schlue, 1989). In such a nicotinic receptor, the ion channel is part of the receptor. Ballanyi and Schlue (1989) analyzed the ion movements underlying receptor activation with ion-sensitive microelectrodes. They found intracellularly a decrease in K^+ activity and an increase in Na^+ and Cl^- activity, as well as a transient acidification. These observations are compatible with a cation channel opening by receptor activation. Cl^- moves in passively and the acidification is probably due to Na^+/H^+ carrier inhibition, because of the reduced Na^+ driving force. Another interesting feature discovered by Ballanyi and Schlue (1989) is the permeability of the acetylcholine-gated channel for cholinergic agents such as choline, tetramethylammonium, and decamethonium. Since acetylcholine is a transmitter in the central nervous system of the leech, the authors suggest that receptor activation leads to K^+ uptake, and therefore contributes to extracellular K^+ buffering. It also can lead to choline uptake into glial cells by movement through the channel, once acetylcholine is broken down by acetylcholine esterase.

Schwann Cells of the Squid and Crayfish. In contrast to other vertebrate and invertebrate glia, the Schwann cells of these species (see Chapter 6, this volume) have low membrane potentials (−40 mV) and respond to axonal stimulation with hyperpolarizations (Villegas, 1984). This Schwann cell hyperpolarization is nicotinic receptor-mediated and K^+ alone is not a sufficient signal to induce the hyperpolarization. The underlying events are a complex mechanism involving two transmitter substances, one of which, acetylcholine, is released by the Schwann cells. Glutamate is stored in a cytoplasmic concentration of about 25 mM in the squid axons and released into the periaxonal space during activity (Lieberman, 1991). Glutamate interacts with several receptor subtypes of the Schwann cell membrane, but only the kainate/quisqualate subreceptor is of interest for this interaction (Evans et al., 1991). Lieberman and

Sanzenbacher (1992) suggested that the receptor activation results in an IP_3-mediated release of Ca^{2+} from intracellular stores into the cytoplasm of the Schwann cell. In these Schwann cells, acetylcholine is stored at a concentration 40 times higher than in the axoplasm (Villegas and Jenden, 1979). Heumann et al. (1981) showed that the Schwann cells are capable of synthesizing acetylcholine. The glutamate-mediated increase in intracellular Ca^{2+} leads to release of acetylcholine from the Schwann cells (Lieberman et al., 1989). This released acetylcholine acts in an autocrine fashion on the Schwann cells themselves via nicotinic receptors. Evans et al. (1985) showed that this receptor activation leads to an increase in cAMP levels via stimulation of adenylyl cyclase. Lieberman (1991) found that cAMP decreases a Cl^- conductance in the Schwann cell membrane, which leads to a long-lasting hyperpolarization. It is assumed that this hyperpolarization assists the Schwann cells in K^+ clearance of the periaxonal space, since the whole cascade is triggered by axonal activity. An obvious effect would be that the reduction in Cl^- conductance increases the relative K^+ permeability, so that the spatial buffer mechanism can work more effectively (see Chapter 47, this volume).

Effects of Acetylcholine on Vertebrate Astrocytes

Receptor Types and Distribution. *In vivo,* about 20% of the astrocytes in the rat brain label for muscarinic receptors. These cells are mainly found in the more superficial strata of the cortex and in the corpus callosum (Van der Zee et al., 1993). There was a correlation between GFAP (glial fibrillary acidic protein) expression and muscarinic receptor occurrence, suggesting that GFAP and muscarinic receptor expression are functionally linked to each other. Astrocytes in gray and white matter showed no differences in this respect. The study also found an increase in muscarinic receptor expression in astrocytes in aged animals.

It was found some time ago that virtually all cultured astrocytes and glioma cells possess acetylcholine receptors (Hamprecht et al., 1976; Repke and Maderspach, 1982). Repke and Maderspach (1982) found muscarinic receptors on astrocytes from chicken cerebral cortex. Murphy et al. (1986) found two muscarinic subtype receptors in cultured astrocytes: M1 and M2. The presence of an M1 subreceptor was inferred from a pirenzepine-inhibited increased turnover of membrane inositol phospholipids. The M2 receptor involvement was suggested by an inhibitory effect on adenylyl cyclase that was not inhibited by pirenzepine.

There is some evidence for nicotinic receptors. Hösli and Hösli (1988) found both nicotinic and muscarinic receptors on astrocytes in organotypic cultures of rat spinal cord and brainstem. The authors used autoradiographic studies that were subsequently confirmed by electrophysiological recordings (see below). They found that many of the astrocytes had muscarinic receptors. A smaller population of the astrocytes had nicotinic receptors. The nicotinic labeling was much weaker than the muscarinic one. Electrophysiological experiments (Hösli et al., 1988) revealed that a single astrocyte could possess both muscarinic and nicotinic receptors.

Activation of Signal Transduction Systems. Murphy et al. (1986) found evidence that M2 subreceptors inhibit the isoproterenol-induced stimulation of adenylyl cyclase. Enkqvist et al. (1989) measured a stimulation of transmembrane Ca^{2+} influx if the astrocytes were exposed to carbachol. In addition, activation of M1 subtype receptors on astrocytes stimulates phospholipase C (Murphy et al., 1986). This will create IP_3 and DG (diacylglycerol). An IP_3 increase will lead to Ca^{2+} mobilization. Such a Ca^{2+} mobilization, in addition to a transmembrane Ca^{2+} influx, was measured by Enkvqist et al. (1989) with the fura-2 method in response to carbachol exposure. An increase in the DG concentration would lead to protein kinase C activation. Furthermore, DeGeorge et al. (1986) reported arachidonic acid production, together with an increase in phosphoinositol metabolism after exposure to acetylcholine. This reflects the activation of the phospholipase C. Gustavsson et al. (1993) found that muscarinic receptor activation leads to phospholipase D activation. Phospholipase D is thought to be more involved in sustained responses of cells through the activation of protein kinase C, whereas Ca^{2+} mobilization is usually transient (Asaoka et al., 1992).

Electrophysiological Effects. Hamprecht et al. (1976) measured the membrane potential in the rat glioma cell line C6. The average resting potential was −28 mV, which is due to a high relative Cl^- conductance (Picker et al., 1981). The application of acetylcholine caused a hyperpolarization in all cells tested. This hyperpolarization was inhibited by atropine but not by D-tubocurarin, suggesting a muscarinic mechanism. However, α-bungaratoxin inhibited the response as well, implicating a nicotinic receptor and contradicting the finding of an underlying muscarinic receptor activation.

Hösli et al. (1988) used organotypic cultures from the spinal cord and brainstem to record membrane potential responses from astrocytes. If acetylcholine was applied, 86 cells hyperpolarized, 22 depolarized, and 27 showed no potential change. The amplitudes

of the responses were between 2 and 8 mV. The authors could not find any dose-response relationship between acetylcholine concentration and amplitude of the response. If muscarine or nicotine was used instead of acetylcholine, there was a similar pattern of hyperpolarization or depolarization and no clear dose-response relationship. When tested on the same astrocyte, acetylcholine, muscarine and nicotine always produced the same effect (either a hyperpolarization or a depolarization). Atropine blocked the muscarinic hyperpolarization, but not the nicotinic. Mecamylamine (a nicotinic antagonist) blocked the hyperpolarization caused by nicotine application. These findings seem to support an earlier autoradiographic demonstration of both nicotinic and muscarinic receptors on these cells (see above). However, the lack of a dose-response relationship and the small amplitudes involved throw the pharmacological validity of the responses into question. No other reports on cholinergic agonist-evoked potential changes or currents in cultured astrocytes are available.

Effect on Cell Functions. From their experiments with invertebrate glial cells, Ballanyi and Schlue (1989) suggest that a nicotinic receptor channel is permeable to choline and that such a channel assists in choline removal (and release) from glial cells. Since there are a few reports of nicotinic receptors in vertebrate astrocytes (see above), such a possibility is worth considering. There is no doubt that astrocytes are capable of choline uptake (see Massarelli et al., 1986). However, a kinetic evaluation of the uptake is compatible with high- and low-affinity carrier systems that appear to be Na^+-dependent (Wong et al., 1983). In general the uptake of choline into glial cells shows characteristics similar to those observed in neurons (for review see Massarelli et al., 1986). There is, however, one report on choline release from glial cultures upon stimulation by *muscarinic* (and not nicotinic) agonists (Kasa and Pakaski, 1987).

Ashkenazi et al. (1989) investigated the effect of carbachol on the DNA synthesis of cultured rat astrocytes. These cells were GFAP-positive and had a protoplasmic morphology. Carbachol stimulated the rate of DNA synthesis in the astrocytes and atropine inhibited this effect, indicating a muscarinic receptor involvement. Oxotromorine is a muscarinic agonist that inhibits adenylyl cyclase but does not stimulate phosphoinositol hydrolysis. This agonist has no effect on astrocytic DNA synthesis. Ashkenazi et al. (1989) used cell lines that expressed muscarinic receptor subtypes that if activated stimulated phosphoinositol hydrolysis. These cell lines showed a stimulation of their DNA synthesis after agonist stimulation. Since it was shown that astrocytes express M1 subtype receptors (Murphy et al., 1986), which stimulate phosphoinositol hydrolysis, it is very likely that the effect of cholinergic agonists on astrocytic DNA synthesis is mediated by these M1 receptors. It is likely that these receptors are involved in astrocytic cell growth during development, which happens between day E14 and P15 (the time period the astrocytes were taken from the brain and cultured in the experiments by Ashkenazi et al., 1989). Acetylcholine could have a function as a signal substance to coordinate the development of astrocytes with the activity of cholinergic neurons.

SEROTONIN

Glial Cells of the Leech

Serotonin is one of the most important neurotransmitters in the leech central nervous system (Lent and Dickinson, 1984). It can easily interchange between central nervous system and blood because the central nervous system of the leech is directly located in the ventral blood sinus and there is no blood-brain barrier. Thus, it is thought that serotonin, released by central neurons, circulates in the blood playing a hormonal or modulator role and has an important function in regulating behavioral states such as arousal (Willard, 1981). Therefore glial cells could very well be exposed to different amounts of serotonin, depending on the overall state of activity in the animal.

It was found that serotonin hyperpolarized leech neuropile glial cells by -7 mV and decreased the input resistance to one-third of its original value (Walz and Schlue, 1982). The response had a reversal potential that behaved like a Nernst potential for K^+ when external K^+ concentrations were changed. Exposure to serotonin led to Cl^- release from the cells (Ballanyi and Schlue, 1990) as well as a shrinkage of the cell volume by 14% (Ballanyi et al., 1990). This indicates that the serotonin-induced changes are due to action on a K^+ conductance, which causes passive KCl and water efflux. Since during neuronal activity these neuropile glial cells take up KCl and swell (Wuttke, 1990), one might speculate that this serotonin-induced KCl release is a possible release process for this transiently stored K^+ (Walz, 1982).

There are indications that serotonin not only modulates ion conductances in leech glia, but also has a metabolic effect. Seal and Pentreath (1985) found that serotonin modulates the glycogen content in the

glial cells of leech segmental ganglia. Such an action is similar to the one in mammalian astrocytes.

Mammalian Astrocytes

Receptor Types and Distribution. Fillion et al. (1980) used a bulk-isolated preparation from horse striatum and reported two binding sites for serotonin. Using kainic acid to destroy postsynaptic binding sites, they found that only one of them was removed. This indicates that one of the binding sites is not located postsynaptically. Since there are no presynaptic binding sites (Whitaker and Deakin, 1981), a glial localization for this serotonin binding site was proposed; It was the lower affinity site (K_D = 10 nM), and the pharmacological profile did not fit with any known subtype receptor. However, the study confirmed that glial cells *in vivo* possess serotonin-binding sites.

Hertz et al. (1979) was the first to report a serotonin-binding site for cultured astrocytes. Whitaker-Azmitia and Azmitia (1986) found that treatment of the cultures with dbcAMP reduced the number of binding sites to one-third. There is a controversy about the subtypes of serotonin receptors found on cultured astrocytes. Much of the earlier work on cultured astrocytes (Hertz et al., 1979; Tardy et al., 1982; Whitaker-Azmitia and Azmitia, 1989) did not use specific antagonists against receptor subtypes. Many studies used methylsergide, which is a 5-HT_1, and a 5-HT_2 receptor antagonist. Thus, in the earlier work, it was proposed that a 5-HT_{1A} and/or 5-HT_{1B} receptor exists in cultured astrocytes. However, Whitaker-Azmitia and Azmitia (1989) and Whitaker-Azmitia et al. (1990) reported the presence of 5-HT_{1A} receptors on astrocytic cultures from various brain regions. This report contradicts the results by other groups especially those by Deecher et al. (1993). However, it should be pointed out that the case for the existence of 5-HT_{1A} receptors is indirect via a functional assay (see below), and not established by binding assays. There was also early evidence for a 5-HT_2 receptor, since ketanserin (a 5-HT_2 antagonist) inhibited serotonin effects (Hosli and Hösli, 1987; Hansson et al., 1987, 1990; Nilsson et al., 1991a; Deecher et al., 1993). In a detailed study by Deecher et al. (1993) using radioligand binding and mRNA analysis, no evidence was found for 5-HT_{1A} or 5-HT_{1B} receptors. They confirmed the occurrence of 5-HT_2 receptors. This occurrence of 5-HT_2 receptors was found for all brain regions studied. Other evidence for the existence of 5-HT_2 receptors, and not 5-HT_1 receptors, comes from studies of second-messenger systems (see below). 5-HT receptors are connected to the adenylyl cyclase, whereas 5-HT_2 receptors are coupled to phosphoinositol hydrolysis. Available evidence clearly connects 5-HT effects with phosphotidylinositol hydrolysis and not with direct effects on adenylyl cyclase (to be discussed in the next section). Thus the available data are heavily in favor of the existence of 5-HT_2 receptors. One cannot exclude the possibility that some heterogeneity exists in the culture systems used by different investigators. This may lead to 5-HT_{1A} or 5-HT_{1B} expression in some of them.

Activation of Signal Transduction Systems. Work by Fillion et al. (1980) suggested a link between the suspected glial binding site and adenylyl cyclase activity. However, neither work on cultured astrocytes nor C6 glioma cells found any evidence for a direct 5-HT receptor link to adenylyl cyclase (Ebersolt et al., 1981; Chneiweiss et al., 1984; Hansson et al., 1987, 1990). Hansson et al. (1990) found that isoproterenol-stimulated accumulation of cAMP was potentiated by a 5-HT_2 receptor activation in cultured astrocytes. Phosphorylation by protein kinase C of the catalytic subunit of adenylyl cyclase is seen as a possible mechanism.

The investigations on cultured astrocytes (Hansson et al., 1987; Murphy and Welk, 1990) and C6 glioma cells (Ananth et al., 1987) all point to an induction of phosphatidylinositol hydrolysis by a 5-HT_2 receptor activation as the mechanism of action for serotonin. This was the mechanism in cultures from regions as diverse as cerebral cortex, striatum, hippocampus, and brainstem. This hydrolysis of phosphatidylinositol should lead, via IP_3, to Ca^{2+} mobilization from internal stores. Several authors measured such a Ca^{2+} mobilization in astrocytes during serotonin exposure (McCarthy and Salm, 1991; Nilsson et al., 1991). It was found for type 2-like (stellate) astrocytes in culture (Dave et al., 1991; Inagaki et al., 1991), although not all cells responded. Glioma cells show a 5-HT_2-mediated Ca^{2+} mobilization (Reiser et al., 1989). The mobilization in the astrocytes was shown to be 5-HT_2 mediated as well (Nilsson et al., 1991b). One study provided evidence that the 5-HT_2 mediated Ca^{2+} increase was not only due to Ca^{2+} mobilization, but that there was also a Ca^{2+} influx component (Nilsson et al., 1991). The serotonin effect on the internal Ca^{2+} stores was seen as the mechanism responsible for the serotonin-induced inhibition of the purinergic receptor-mediated arachidonic acid release (Murphy and Welk, 1990).

Thus, at least from the point of view of cell culture studies, there can be little doubt that there is 5-HT_2-mediated hydrolysis of phosphatidylinositol accompanied by Ca^{2+} mobilization. Direct effects on the adenylyl cyclase activity have been ruled out. What

is lacking is confirmation of these results from *in situ* systems. At least one study confirmed a 5-HT_2-mediated phosphatidylinositol hydrolysis in brain tissue (Conn and Sanders-Bush, 1985).

Electrophysiological Effects. In explant cultures from striatum, brainstem, and spinal cord Hösli and Hösli (1987) were able to show that 64% of the astrocytes hyperpolarized (1–8 mV), 13% depolarized, and 23% showed no change in the membrane potential in response to serotonin application. Since ketanserin reversibly antagonized the hyperpolarizations, a 5-HT_2-mediated mechanism appeared likely. This study is contradicted by another, which did not find any electrical changes in cultured astrocytes when serotonin was applied (Kettenmann et al., 1984).

Rat glioma cell lines have a lower membrane potential than astrocytes due to a higher relative Cl^- conductance (Picker et al., 1981; Wolpaw and Martin, 1984). These cells react to serotonin exposure with about −20 mV hyperpolarization and with decreases in their input resistance (Ogura and Amano, 1984). There was a clear desensitization and the reversal potential was close to the K^+ equilibrium potential. A low concentration of quinidine, a Ca^{2+}-dependent K^+ channel blocker, inhibited the response. Further it was found that there was an intracellular Ca^{2+} mobilization (Sugino et al., 1984; Ogura et al., 1986; Reiser et al., 1989). The receptor activation mediates a stimulation of phospholipase C, leading among other products to IP_3, a mediator of Ca^{2+} mobilization (Ananth et al., 1987). Thus for these glioma cell lines the following sequence of events emerges:

1. A 5-HT_2 receptor is activated.
2. Increased phospholipase C activity leads to IP_3 production.
3. IP_3 mediates Ca^{2+} mobilization.
4. Increased cytosolic Ca^{2+} concentrations opens Ca^{2+}-dependent K^+ channels.
5. The increased K^+ conductance causes a hyperpolarization due to the low relative K^+ permeability during resting conditions.

Serotonin Receptors and Growth and Development. There is evidence that serotonin is used as differentiation signal for some embryonic neurons (Lauder et al., 1982). This may involve mediation by glial-derived factors (Whitaker-Azmitia et al., 1990). Thus, when astrocytic cultures from brainstem or cortex are treated with 5-HT_{1A} agonists, they release one or several factors, that when applied to developing serotonergic neurons enhance their development (Whitaker-Azmitia and Azmitia, 1989). Development was measured as an increase in serotonin uptake. Furthermore, it was shown with a specific antibody that at least one of the factors released by astrocytes is the protein S-100β (Whitaker-Azmitia et al., 1990). S-100β stimulates both the differentiation and survival of neurons and the proliferation of astrocytes themselves (Azmitia et al., 1992). There is also some *in vivo* evidence for such an interaction. Rats lesioned with 5,7-DHT, a selective toxin for serotonergic neurons produced an 80% increase in S-100β levels, when treated with the 5-HT_{1A} receptor agonist (Azmitia et al., 1990).

A further test of such involvement of 5-HT receptor mediated release of glia-derived factors in neuronal development was undertaken by Liu and Luder (1992). Serotonin exposure of cultured raphe (serotonergic) neurons and mesencephalic dopamine neurons had larger effects on survival, and cell soma size, in neuronal-glial cocultures. There were some region-specific differences that led to the conclusion that raphe and mesencephalic glia may express different capacities for such an interaction with serotonin and subsequent release of factors influencing neuronal development.

Other Effects on Functional Variables. Several other effects of serotonin exposure to astrocytic function have been described, but none was studied in detail. A glial-enriched brain fraction was used to study Na^+/K^+-ATPase activity (Mercado and Hernandez, 1992). The authors postulated that serotonin exposure will lead to an activation of the glial Na^+ pump through the exposure of more enzymatic active sites. The effects are significant but not dramatic: K_m increased from 6.0 to 9.3 mM and V_{max} from 11.2 to 14.5 μmole $P_i \times mg^{-1}$ protein $\times h^{-1}$ when exposed to a relatively high serotonin concentration of 1 mM.

Hertz et al. (1989) demonstrated that serotonin exposure of astrocytes inhibited high K^+-induced glutamate release. Again, the serotonin concentration was high (1 mM). This effect, however, could be important in metabolic interactions. In this context it is of interest that Cambray-Deakin et al. (1988) have shown that serotonin has no effect on the astrocytic glycogen content. However, if the cultures are reserpine-treated and therefore have a higher glycogen content, serotonin decreases this elevated content by 28%. Thus, serotonin was shown to evoke glycogenolysis under certain circumstances, although its potency is far less than, for example, that of norepinephrine.

CONCLUSIONS

A most interesting feature is the ability of invertebrate Schwann cells to synthesize acetylcholine and release it in response to an axonal signal. Moreover, acetylcholine then subsequently acts on glial conductances. These findings, together with those in leech glial cells, suggest that acetylcholine is a controlling signal in K^+ homeostasis in the invertebrate nervous system.

Muscarinic M1 and M2 receptors and their signal transduction systems have been described in the mammalian brain. There are also some reports of nicotinic receptors on glia. The only convincing experimental evidence that glial muscarinic receptors are functionally important pertains to the control of the development of astrocytes.

Serotonin seems to regulate glial ion content and volume in the leech central nervous system, which may implicate its involvement in ion homeostasis. In the mammalian central nervous system electrical effects seem negligible. There is good evidence for the existence of 5-HT_2 receptors in astrocytes and their involvement in phosphatidylinosite hydrolysis and Ca^{2+} mobilization. No clear concept has emerged about the function of this signal system. Several reports show a close relationship between serotonergic receptor-evoked release of glial factors (i.e., S-100β) and their regulatory influence on neurons. In this case, however, a postulated 5-HT_{1A} receptor seems to be responsible.

Most interesting might be a possible interaction between these transmitter receptors and uptake systems. Ballanyi and Schlue (1989) found that the nicotinic receptor-channel complex can assist in uptake (and maybe release) of choline into glia. Deecher et al. (1993) speculated about a possible interaction between 5-HT_2 receptors and serotonin uptake systems in the mammalian brain: Fluoxetine, an inhibitor of serotonin uptake, seems to decrease the number of the glial 5-HT_2 binding sites in the brain (Asakura and Tsukamoto, 1985).

Taken together, the available evidence suggests that crucial interactions between neurons and glial cells occur and that acetylcholine and serotonin are involved, although the evidence is not yet as convincing as in the cases of glutamate and GABA.

The author is the recipient of a Scientist Award from the Medical Research Council of Canada. Dr. Nigel H. West is thanked for critically reviewing the text.

23 Astroglial adrenergic receptors: expression and function

KEN D. MCCARTHY, KRISTIAN ENKVIST, AND YANPING SHAO

While glial cells as a distinct component of the central nervous system were described over a hundred years ago (Virchow, 1858), it is surprising how little we know about the role of these cells in brain function. Shortly after the turn of the century, Lugaro (1907) suggested that glia may play a role in neuronal communication. This speculative report raised the possibility that glia may terminate the action of neurochemicals released from neurons. Many years elapsed before investigators were able to develop preparations that could be used to assess the functions of glia. A major difficulty in assessing the role of astrocytes in central nervous system function is the lack of model systems for studying the properties of these cells *in vivo*. It is very clear from research in many laboratories that astroglia exhibit a wide variety of neurotransmitter receptor and uptake systems, ion channels, growth factors, adhesion molecules, and metabolic processes that may be critical for the normal development and function of the central nervous system. To date, however, no astrocytic functions have been proven to be critical for the function of the adult central nervous system. The lack of information on the role of astrocytes in brain function most likely stems from the difficulty of studying these cells *in vivo*. A similar void was present 20 to 25 years ago concerning the properties of astroglial cells *in vitro*. Through a number of technical and conceptual advances, we are now by comparison overwhelmed with the diverse properties of astroglia that have been established by studies of these cells *in vitro*. Whether or not these properties translate into astrocytic functions *in vivo* remains the quest of many neurobiologists.

EARLY EVIDENCE FOR NEUROTRANSMITTER RECEPTORS ON GLIA

Probably the most important breakthrough since the description of glia by Virchow in the late nineteenth century was the development of methods that could be used to study the properties of these cells *in vitro*. These methods appeared in two stages: first, the identification of transformed cell lines that exhibited glial characteristics *in vitro* (Clark and Perkins, 1971; Gilman and Nirenberg, 1971) and second, the preparation of cultures of nontransformed glia from brain tissue (Booher and Sensenbrenner, 1972; McCarthy and de Vellis, 1980). In 1971, two groups (Clark and Perkins, 1971; Gilman and Nirenberg, 1971) reported that cell lines thought to be of glial origin responded to adrenergic receptor agonists with an increase in cyclic AMP. These studies surprised many neurobiologists who had assumed that neurotransmitter receptors in the central nervous system would be restricted to neuronal elements. One possible explanation for these findings was that the glial cell lines were derived from progenitor cells that exhibit the characteristics of both neurons and glia. In 1972, however, Gilman and Schrier demonstrated that cultures prepared from fetal brain also responded to adrenergic receptor agonists with an increase in cyclic AMP levels and conditions that promoted nonneuronal cell survival led to a greater degree of stimulation. These seminal studies strongly suggested that glial cells had the potential to respond to neurotransmitters released from neurons. Many neurobiologists held to the view that these findings reflected the responses of nonglial cells contained within the population of brain cells. As these studies were being reported, other investigators were developing methods that could be used to prepare purified cultures of astroglia (McCarthy and de Vellis, 1980). These methods and the growing availability of astroglial-specific immunological markers (Bignami et al., 1972; Norenberg and Martinez-Hernandez, 1979) opened the door for an ever-increasing number of neurobiologists to explore the diverse properties of these cells.

During the late 1970s and early 1980s a large number of investigators assessed the ability of astroglial cells to respond to different neuroligands with an increase in cyclic AMP (van Calker and Hamprecht, 1981; van Calker et al., 1978; McCarthy and de Vellis, 1978, 1979; Ebersolt et al., 1981).

The results of these studies demonstrated that essentially all receptors known to affect cyclic nucleotide levels affected this second-messenger system in astroglia. Furthermore, the finding that the stimulation of cyclic AMP levels by one ligand could be modulated by an alternate ligand (van Calker et al., 1978; McCarthy and de Vellis, 1978, 1979; Evans et al., 1984) suggested that individual astroglia exhibited multiple neuroligand receptor systems. Through the 1980s and early 1990s investigators continued to assess the expression of receptor systems either by measuring alternate second-messenger systems (Pearce et al., 1985; Pearce et al., 1986; M. Enkvist et al., 1989a, 1989b; Salm et al., 1990a), directly labeling receptors with isotopically labeled ligands (McCarthy and Harden, 1981; Harden and McCarthy, 1982; Torrens et al., 1986; Yeung et al., 1991) or electrophysiological methods (Walz, 1989; Berger et al., 1992; Bowman et al., 1992; Gimpl et al., 1992; Magoski and Walz, 1992). As these studies continued it became clear that the issue was not which neuroligand receptors were present, but rather, which receptors were missing from astroglia. Currently, there appears to be good agreement that astroglia lack the NMDA (*N*-methyl-D-aspartate) excitatory amino acid receptor *in vitro*. However, recent studies suggest that astrocytes *in vivo* may exhibit a distinct form of the NMDA receptor (Müller et al., 1993).

ASTROGLIA ARE HETEROGENEOUS WITH RESPECT TO THEIR EXPRESSION OF NEUROLIGAND SIGNAL TRANSDUCTION SYSTEMS

Assuming that astroglia exhibit receptors *in vivo* to respond to locally released neurotransmitters, the repertoire of receptors exhibited by these cells should vary within and between brain regions. Initial attempts to test this hypothesis compared the ability of different neuroligands to affect second messengers in populations of astroglia prepared from different brain regions (Cholewinski, and Wilkin, 1988; Wilkin et al., 1990). The results of these studies supported the view that certain agonists were more effective in one brain region than another (Cholewinski, and Wilkin, 1988; Wilkin et al., 1990); however, there were few examples of qualitative differences in the responsiveness of astroglia prepared from different brain regions. To examine the question of receptor heterogeneity in greater detail, methods were developed that enabled the quantitative measurement of the number of neuroligand binding sites on individual immunocytochemically defined cells *in vitro*. Methods were developed to quantify both alpha- and beta-adrenergic receptors using iodinated receptor ligands (Royds et al., 1982; Lerea and McCarthy, 1989). The results of experiments using the beta-adrenergic receptor (β-AR) selective ligand, cyanopindolol, indicate that all type 1-like astroglia (Raff, 1989) examined exhibit β-ARs (Burgess et al., 1985; Burgess and McCarthy, 1985). To date, astroglia isolated from cerebral cortex, cerebellum, hippocampus, and spinal cord have been examined in these studies. In contrast, type 2-like astroglia do not appear to exhibit β-ARs (Burgess and McCarthy, 1985). As type 1- and type 2-like astroglia appear to represent separate glial lineages (Raff, 1989), these findings suggest that there is little heterogeneity in the expression of β-ARs within either lineage of these two groups of glial fibrillary acidic protein (GFAP) positive cells. Furthermore, the ubiquitous expression of β-AR by type 1-like astroglia suggests that whatever functions are influenced by this receptor system, they are common throughout the brain. Neither neurons nor oligodendroglia appear to exhibit a significant number of β-AR binding sites *in vitro* (Burgess et al., 1985).

The expression of alpha$_1$-adrenergic receptors (α_1-ARs) by neural cells was measured using the receptor ligand [^{125}I]HEAT (Lerea and McCarthy, 1989). The results of these studies suggest that both type 1- and type 2-like astroglia are heterogeneous with respect to their expression of this adrenergic receptor system (Lerea and McCarthy, 1989). Interestingly, type 1-like astroglia exhibited a very large range in the density of α_1-ARs expressed. Within a single microscopic field, astroglia were observed to exhibit densities ranging from zero to several thousand binding sites per thousand square micrometers. Approximately 70% of type 1- and type 2-like astroglia exhibit α_1-AR binding sites above nonspecific levels (Lerea and McCarthy, 1989). No evidence for receptor clustering has been observed for either β-ARs or α_1-ARs on astroglia (Lerea and McCarthy, 1989; Burgess et al., 1985). The finding that astroglia vary both qualitatively and quantitatively in the expression of β- and α_1-ARs suggests that these receptor systems are not expressed in response to *in vitro* culture conditions.

It is likely that full astroglial differentiation requires association with neurons. Therefore, experiments were designed to examine the effect of neurons on the expression of α_1-ARs by astroglia. In these experiments, cocultures of neurons and astroglia were prepared from hippocampus and grown under conditions that resulted in astroglia growing both in direct apposition to neurons and away from neurons (Lerea and McCarthy, 1990). These experi-

ments revealed two interesting findings. First, astroglia in direct contact with hippocampal neurons often assumed an elongated morphology that closely resembled that of neurons (Lerea and McCarthy, 1990). These elongated astroglia did not resemble type 2-like astroglia in their morphology. Furthermore, direct contact between neurons and astroglia was required to induce the morphological change in astroglia, as those separated from neurons by only a few micrometers failed to become elongated. Second, approximately 70% of astroglia growing in direct contact with neurons continued to exhibit α_1-AR binding sites. Overall, the results of these studies indicate that astroglia are heterogeneous in their expression of binding sites for α_1-AR ligands and that these cells continue to express α_1-ARs when grown in intimate association with neurons. These findings support the premise that α_1-ARs are distributed similarly on astrocytes *in vivo*.

As evidence accumulated that astroglia exhibit a large number of receptor systems, an interesting question emerged: Can pharmacologically distinct subsets of these cells be identified? To address this issue, the influence of neuroligands on calcium mobilization in groups of individual astroglia in nonconfluent cultures was examined. In these experiments, astroglia were loaded with the calcium indicator dye fura-2, and the response of individual cells was monitored with a video-based imaging system (Salm and McCarthy, 1990b; McCarthy and Salm, 1991). Through these experiments it became clear that astroglia exhibit a number of different receptor systems linked to calcium regulation and that marked heterogeneity exists among the cells with respect to their ability to respond to neuroligands with a rise in intracellular calcium (McCarthy and Salm, 1991). Neuroligands effective in increasing calcium levels in astroglia include those that stimulate alpha$_1$- and alpha$_2$-adrenergic, -histaminergic, -muscarinic, -P_{2Y} purinergic, -glutaminergic, and -serotonergic receptors (McCarthy and Salm, 1991). No evidence for the grouping of subsets of these receptor systems among astroglia was observed. In general, the efficacy of different neuroligands was similar with respect to their ability to increase calcium levels in astroglia. However, the percentage of astroglia responding to the different neuroligands with a rise in intracellular calcium levels varied markedly (McCarthy and Salm, 1991). Most of the neuroligands examined appeared to increase intracellular calcium levels both through the release of internal stores and the opening of plasma membrane calcium channels (Salm and McCarthy, 1990b).

The observation that very few examples exist of cells switching their receptor phenotype suggested that the pharmacological heterogeneity of astroglia was likely to be "locked" and to reflect distinct and stable subsets of cells. Two approaches were used to test this hypothesis. First, astroglia were plated at cloning density, allowed to develop into clones containing from 2 to 16 cells, and then assessed for their ability to respond to neuroligands with a rise in intracellular calcium levels. In marked contrast to expectations, the individual cells of an astroglial clone varied in their ability to respond to neuroligands with a rise in Ca_i^{2+}. For example, immediately following the division of a parent cell, the two daughter cells were qualitatively distinct with respect to their ability to respond to neuroligands with a rise in Ca_i^{2+} (Shao and McCarthy, 1993). The design of these experiments left open the possibility that astroglia of a single clone would eventually express the same set of receptor systems if maintained *in vitro* for an extended period of time. To address this question, astroglia were transfected with a retrovirus that enabled selection for transfected clones via antibiotic resistance. The results of these experiments indicated that astroglia within a single clone remain pharmacologically distinct after 4 weeks *in vitro* (Shao and McCarthy, 1993). These findings indicate that intrinsic clocks persist in astroglia *in vitro,* which lead to the diversification of these cells. These experiments did not directly address the question of whether the receptor signaling systems of individual astroglia change over time. This question was examined by monitoring the calcium responsiveness of the same individual astroglia within clones at intervals of 1 to 3 days. The results of these experiments indicated that the ability of individual astroglia to respond to neuroligands changes over time *in vitro.* In general, astroglia develop sensitivity to α_1-AR agonists during the first week *in vitro* (Shao and McCarthy, 1993). However, it is evident that cells may either develop or lose their ability to respond to a neuroligand over the course of only a few days *in vitro.*

It became apparent during the course of these experiments that astroglia tended to lose their sensitivity to carbachol (a muscarinic cholinergic agonist) over several days of testing. The initial assumption was that the loss in sensitivity to carbachol reflected a developmental process inherent in astroglia. However, a similar percentage of previously untested astroglia responded to carbachol with a rise in Ca_i^{2+} after 1, 2, or 3 weeks *in vitro* (Shao and McCarthy, 1993). It is now apparent that brief stimulation of astroglia with carbachol (5 minutes per day for 3 days; 1 mM) triggers the downregulation of muscarinic cholinergic signal transduction (Shao and McCarthy, 1993). These findings suggest that brief exposure to calcium

mobilizing ligands selectively affects astroglial muscarinic cholinergic receptor expression (Shao and McCarthy, 1993). To date, similar findings with other cells that exhibit muscarinic receptors linked to calcium mobilization have not been observed. Collectively, these findings indicate that both intrinsic and extrinsic signals affect the expression of astroglial signal transduction systems.

ASTROGLIA EXHIBIT AN ALL-OR-NOTHING CALCIUM RESPONSE TO ALPHA$_1$-ADRENERGIC RECEPTOR STIMULATION

Previous studies indicated that approximately 70% of type 1-like astroglia exhibit α_1-AR binding sites (Lerea and McCarthy, 1989). A surprising finding in those studies was the wide range in the density of α_1-AR binding sites (a few over background to several thousand per 1000 μm^2) exhibited by astroglia. Interestingly, subsequent experiments found that a similar percentage of the cells responded to α_1-AR selective ligands with an increase in Ca_i^{2+}. A series of experiments were designed to examine the quantitative relationship between the density of α_1-AR binding sites and the ability of astroglia to respond to α_1-AR selective ligands with a rise in Ca_i^{2+}. In these experiments, individual astroglia were first analyzed for their Ca^{2+} sensitivity to phenylephrine (an α_1-AR-selective ligand) and then their expression of α_1-AR binding sites and GFAP were determined. Surprisingly, little correlation was found between the density of α_1-ARs and the magnitude of the rise in Ca_i^{2+} in astroglia following treatment with phenylephrine (Figures 23-1 and 23-2). Dose-effect experiments supported the poor correlation between the number of α_1-ARs occupied and the magnitude of the Ca_i^{2+} response in these cells (Figure 23-3). Together, the results of these studies suggest that astroglia need only a few α_1-AR binding sites occupied to elicit a full Ca^{2+} response. In contrast to the magnitude of the Ca^{2+} response, both the probability of responding and the latency to response (the time between drug addition and initial rise in Ca_i^{2+}) correlated strongly with the density of α_1-ARs exhibited by astroglia and the dose of phenylephrine applied (Figures 23-4 and 23-5). These findings suggest that activation of α_1-ARs results in the accumulation of a second messenger (presumably IP_3), which must reach a threshold concentration before eliciting what is then an all-or-nothing Ca^{2+} response. Further-

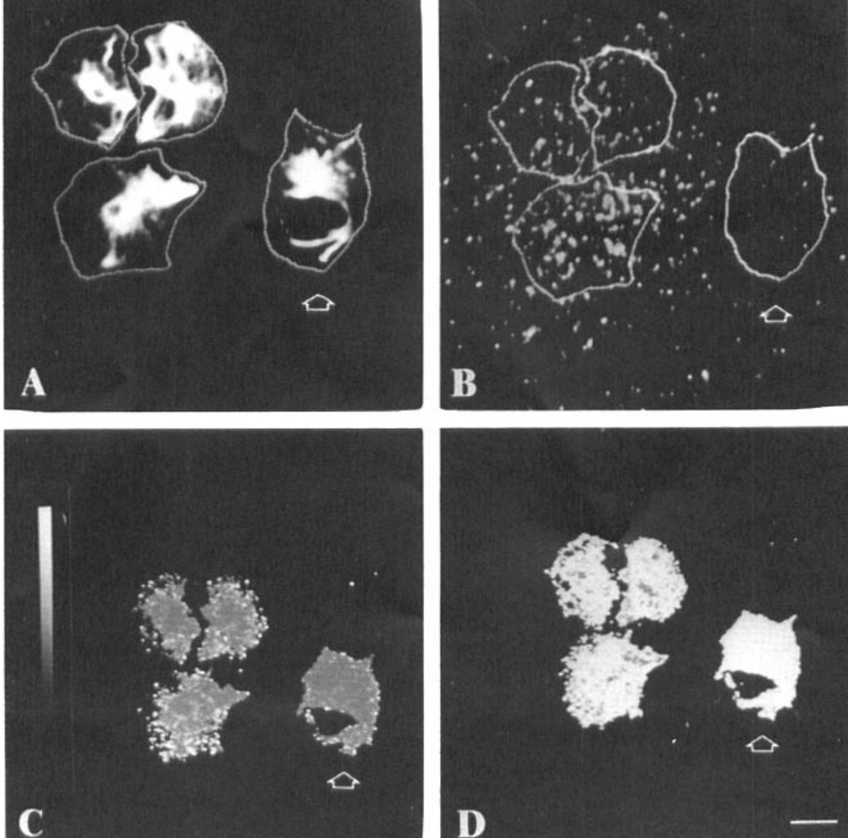

FIG. 23-1. Ca^{2+} responses in astroglia with different α_1-AR densities. Cells in primary culture were loaded with fura-2 and tested for Ca^{2+} responses, and subsequently processed for combined GFAP immunocytochemistry and α_1-AR receptor autoradiography. Digitized images show 4 GFAP positive cells (A) with various grain densities (B). Following addition of 10 μM phenylephrine, all cells increased $[Ca^{2+}]_i$ from the basal (C) to the maximal level within 5 seconds (D). Bar = 10 μm.

FIG. 23-2. Ca^{2+} responses in individual astroglial cells as a function of α_1-AR density. Each dot represents a cell that was exposed to 1 μM phenylephrine and subsequently processed for the α_1-AR binding autoradiography. A total of 107 cells that had an α_1-AR density above the nonspecific level are presented. The *y*-axis represents the increase in Ca_i^{2+} levels above basal levels (peak response − basal level).

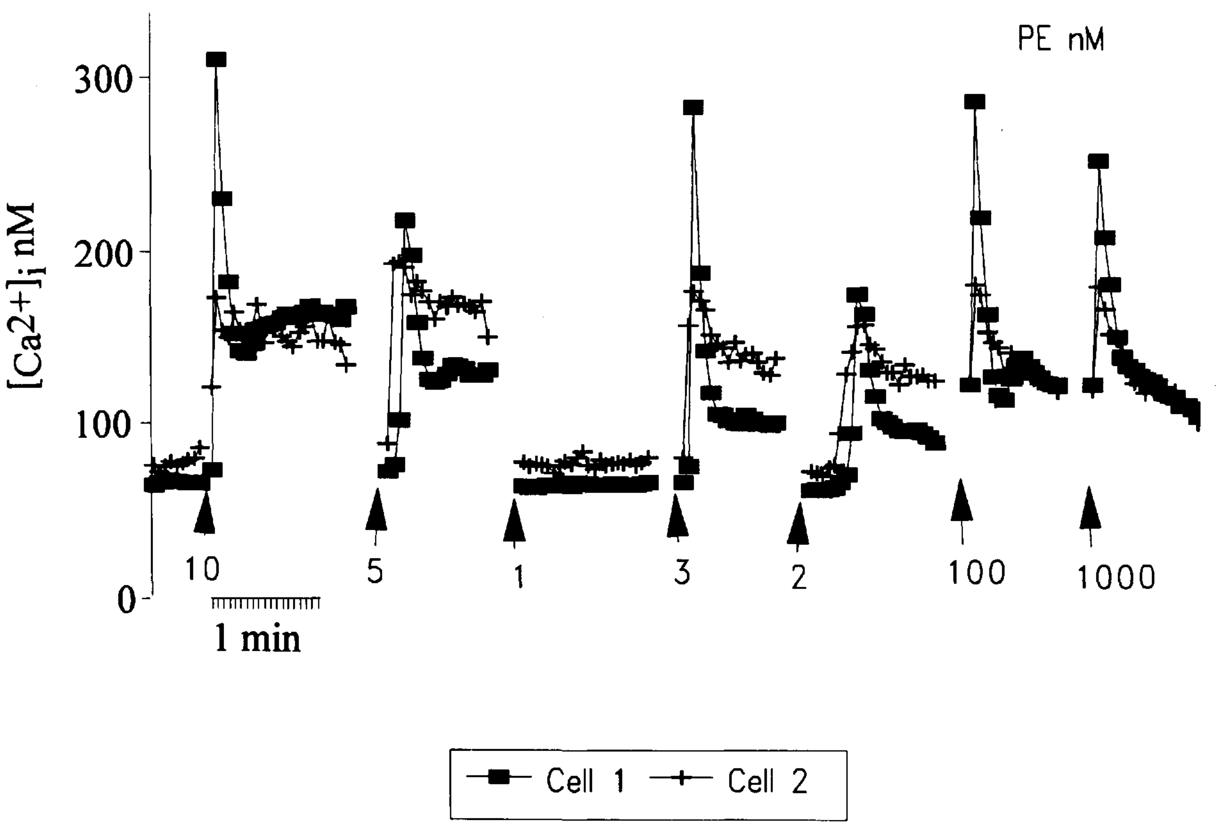

FIG. 23-3. Dose-response of astroglial cells to various concentrations of phenylephrine. The two cells were treated with phenylephrine with a change of the full-bath solution (*arrows*). Between each treatment, the cells were rinsed with ligand-free HBSS 3 times, and incubated for at least 5 minutes. The sampling rate is 3 seconds per measurement.

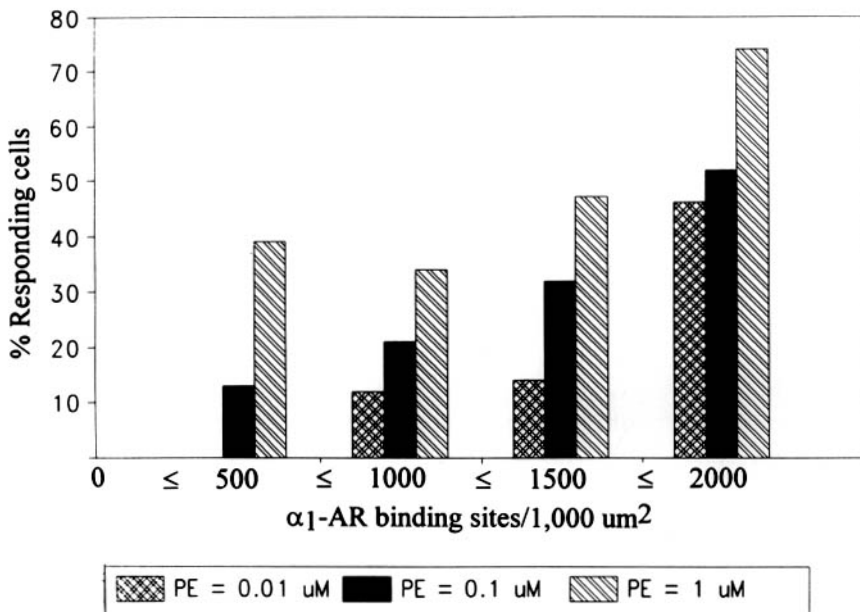

FIG. 23-4. Relative frequency of astroglial responsiveness to various doses of phenylephrine in relation to the α_1-AR density. Cells were treated with 10, 100, and 1000 nM phenylephrine successively, and subsequently processed for α_1-AR binding autoradiography. Cells were grouped according to their α_1-AR density (bin width = 500 binding sites per 1000 μm^2, n = 36).

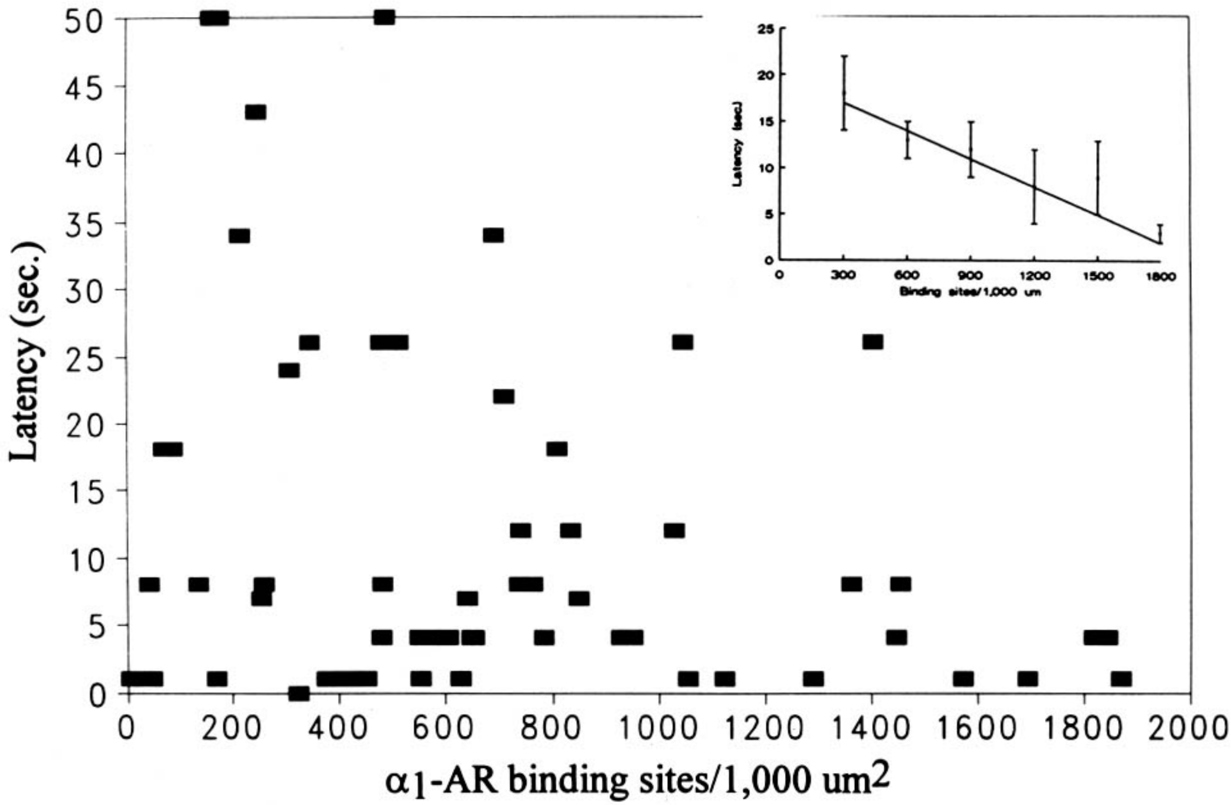

FIG. 23-5. Relationship between latencies of Ca^{2+} responses and α_1-AR densities on individual astroglial cells. Each dot represents the time between the addition of the ligand and the onset of the response plotted against the α_1-AR densities of 51 cells that responded to 10 μM phenylephrine. Inset: The data are MEAN ± SEM of the average time of cells grouped according to their α_1-AR density with the bin width of 300 binding sites per 1000 μm^2. The line is derived from linear regression with a correlation coefficient of 0.95.

more, the observation that the probability of responding is correlated with the density of α_1-AR binding sites suggests that the rate of second-messenger accumulation is important in determining whether or not cells respond to α_1-AR stimulation with a rise in Ca_i^{2+}. One possibility is that IP_3 must accumulate to a given concentration to elicit a Ca_i^{2+} response. When only a few α_1-ARs are available for stimulating phospholipase C, cells desensitize prior to accumulating sufficient IP_3 for Ca^{2+} release. The finding that astroglia exhibit an all-or-nothing response suggests that feed-forward processes are involved in the regulation of Ca_i^{2+} in these cells. The observation that astroglia with low α_1-AR densities occasionally respond to phenylephrine with a rise in Ca_i^{2+} suggests that other processes are also important in causing Ca^{2+} release from internal stores. One possible explanation for this finding would be spatial coupling of the different components (α_1-ARs, G proteins, PLC, IP_3-sensitive stores) required for Ca^{2+} release. The observation that ligands tend to initially stimulate an increase in Ca_i^{2+} from a given point in astroglia support the view that one or more of the components of the response system are spatially restricted.

Collectively, the above findings suggest that the regulation of Ca^{2+} responses in astroglia quite closely resembles the regulation of action potentials in neurons. That is, ligands induce an all-or-nothing Ca^{2+} response, which initiates from a given point in the cells and then propagates through the cell in a regenerative manner. Furthermore, the effect of different ligands that increase IP_3 levels is integrated such that cells that would not respond to either ligand alone respond to the combination with a full Ca^{2+} response. Finally, like the generation of action potentials in neurons, both the probability of responding and the latency to response are correlated with the number of occupied receptors in astroglia. We envision that *in vivo* astrocytes integrate the stimulation of multiple ligands to reach a threshold level of IP_3, which then leads to a burst of Ca_i^{2+}, which then moves through individual astroglia and the astrocytic syncytium in a regenerative manner. The role that these Ca_i^{2+} waves play in brain physiology remains an important question in glial biology (see Chapter 17).

ASTROCYTES *IN VIVO* EXHIBIT ALPHA$_1$- AND BETA-ADRENERGIC RECEPTORS

While abundant evidence exists that astroglia exhibit a large number of receptor systems *in vitro*, it has been much more difficult to establish that mature astrocytes *in vivo* exhibit similar receptor systems. The lack of data supporting the presence of receptors on astrocytes *in vivo* stems in large part from the difficulty in preparing purified preparations of astrocytes from mature brain tissue. However, two different approaches have been used to study the expression of adrenergic receptors by mature astrocytes and both suggest that astrocytes exhibit these receptors (Salm and McCarthy, 1989; Aoki and Pickel, 1992; Shao and Sutin, 1992). The β-AR selective ligand [^{125}I]cyanopindolol and dry-mount autoradiography were used to examine the expression of β-ARs by individual fibrous and protoplasmic astrocytes isolated from adult rat brain. The results of these studies indicate that all astrocytes isolated and identified by their GFAP staining exhibit β-ARs (Salm and McCarthy, 1989). Similar findings were reported by Shao and Sutin (1992) for glial cells of the trigeminal motor nucleus. Other investigators have used antibodies to β-ARs to demonstrate that glial elements exhibit this receptor subtype (Aoki and Pickel, 1992). Interestingly, an antibody directed against the β_2-AR subtype was used in these experiments. Results from these studies suggest that β_2-ARs are not uniformly expressed by astrocytes *in vivo*. Furthermore, earlier studies suggested that astroglia in culture exhibit the β_1-AR subtype. While additional experiments with alternate receptor subtype specific antibodies are required, present data support the view that the subtype of β-ARs expressed by astrocytes may change during development. Regardless of the receptor subtype, it is clear that astrocytes *in vivo* exhibit beta-adrenergic receptors and are a target for norepinephrine released in brain. A similar conclusion can be drawn from studies using freshly isolated mature astrocytes and [^{125}I]HEAT to label α_1-ARs (Shao and Sutin, 1992). In these experiments Shao and Sutin (1992) found that a subpopulation of mature astrocytes isolated from brainstem exhibited α_1-ARs.

REGULATION OF GAP JUNCTIONS IN ASTROGLIA BY LIGANDS LINKED TO THE ACTIVATION OF PROTEIN KINASE C

Numerous studies indicate that astroglia *in vitro* (Fischer and Kettenmann, 1985; Sontheimer et al., 1990; Dermietzel et al., 1991) and astrocytes *in vivo* (Connors et al., 1984) are often connected to one another via gap junctions. In astrocytes, gap junctions are composed of 12 units of connexin43, 6 contributed from each of the coupled astrocytes (Yamamoto et al., 1990; Bennett et al., 1991; see Chapter 19, this volume). Connexin43 is also the gap junction protein responsible for the formation of gap junctions in

heart. A number of reports indicate that waves of Ca^{2+} move through an astroglial syncytium via gap junctions (Cornell-Bell et al., 1990; Charles et al., 1991). Similar Ca^{2+} waves have been reported in astrocytes in brain slice cultures (Dani et al., 1992). These findings suggest that an extraneuronal communication network consisting of coupled astrocytes and Ca^{2+} waves may exist in brain. There seems to be two broad views of how this network might work. First, astrocytic signaling over distances via Ca^{2+} waves could be directional, with gap junctions open along certain paths and closed along others. Alternatively, astrocytes may be coupled in a restricted region such that a response in an individual astrocyte results in the activation of a group of astrocytes but without a directional component. In either case, regulation of the opening and closing of astrocytic gap junctions would influence the degree of astrocytic activation. Other investigators have reported that second-messenger systems effectors (e.g., protein kinase C (PKC), protein kinase A (PKA), Ca^{2+}) regulate the opening and closing of gap junctions (Bennett et al., 1991). A series of experiments were completed to examine the effect of treatments that stimulate PKC activity on gap junction communication between astroglia. Two different approaches were used to examine gap junction communication between astroglia. First, the number of cells coupled was determined following injection of a single cell with lucifer yellow. Second, the distance traveled by calcium waves through astroglia following the stimulation of a single cell with a mechanical probe was measured. The results of these experiments indicate that treatments that stimulate PKC activity decrease gap junction communication between astroglia (Enkvist and McCarthy, 1992). When PKC was downregulated by a 24-hour pretreatment with phorbol 12-myristate-13-acetate (PMA), the reduction in gap junction communication caused by brief treatment with either PMA or P_{2Y}-purinergic receptor agonists (which activate PLC in most astroglia) was blocked (Enkvist and McCarthy, 1992). Similar findings have been reported by Giaume et al. (1991). These findings suggest that the coupling of astrocytes *in vivo* may be regulated by neurotransmitters released during neuronal activity. The regulation of gap junction communication between astrocytes may play an important role in events ranging from spatial buffering to the release of trophic factors (see Chapter 19, this volume).

Dye coupling between astroglia was recently reported to be increased by membrane depolarization (Enkvist and McCarthy, 1994). In these experiments astroglia were depolarized by either increasing the concentration of extracellular K^+ or by adding ionophores and the degree of astroglial coupling measured following injections with lucifer yellow. Increasing extracellular K^+ led to a dose-dependent increase in dye coupling between astroglia (Figure 23-6). Gramicidin, a nonspecific cation ionophore that leads to depolarization (Ishii and Volpe, 1992), also increased dye coupling between astroglia (Figure 23-6). In contrast, valinomycin, a K^+ specific ionophore that hyperpolarizes cells, decreased dye coupling between astroglia (Figure 23-6). Finally, treatment with either glutamate, kainate or quisqualate, ligands known to depolarize astroglia (Enkvist et al., 1988), also led to an increase in gap junction communication between astroglia (Figure 23-7). Overall, these findings suggest that the degree of coupling between astrocytes *in vivo* may be regulated by neuronal activity and that specific pathways of extraneuronal communication within the astrocytic syncytium may be important in brain function.

PHYSIOLOGICAL SIGNIFICANCE OF NEUROLIGAND RECEPTORS ON ASTROCYTES

While it is clear that both astroglia *in vitro* and astrocytes *in vivo* exhibit adrenergic receptors, the role that these and other receptor systems play in brain function is less evident. Most studies aimed at elucidating the role of astrocytic receptors in brain function have utilized primary cultures of astroglia. While these *in vitro* preparations provide useful insight into the potential function of astrocytes *in vivo*, it remains uncertain whether properties expressed *in vitro* accurately reflect those expressed *in vivo*. However, it is very likely that the diverse properties characteristic of astroglia *in vitro* are representative of astrocytes *in vivo* at some stage of development.

Early studies with glioma cell lines suggested that glial cells may be important in supporting neurons through the release of neurotrophic factors (Schwartz et al., 1977). It is now clear from the work of many investigators that glial cells synthesize and release a number of different factors that are necessary for neuronal survival and growth (Varon et al., 1987; Ferrara et al., 1988; Houlgatte et al., 1989; Schwartz and Mishler, 1990; Zafra et al., 1992). Neuroactive factors released from astroglia include nerve growth factor, enkephalin peptides, angiotensinogen, taurine, nitric oxide, eicosanoids, S-100, ciliary neurotrophic factor, brain-derived neurotrophic factor, and neurotrophin 3 (Martin, 1992). Additional neuroactive substances have been reported to be present in astroglia and may also be released to affect neuronal activity (Martin, 1992; see Chapters 48 and 49, this volume). These findings strongly sug-

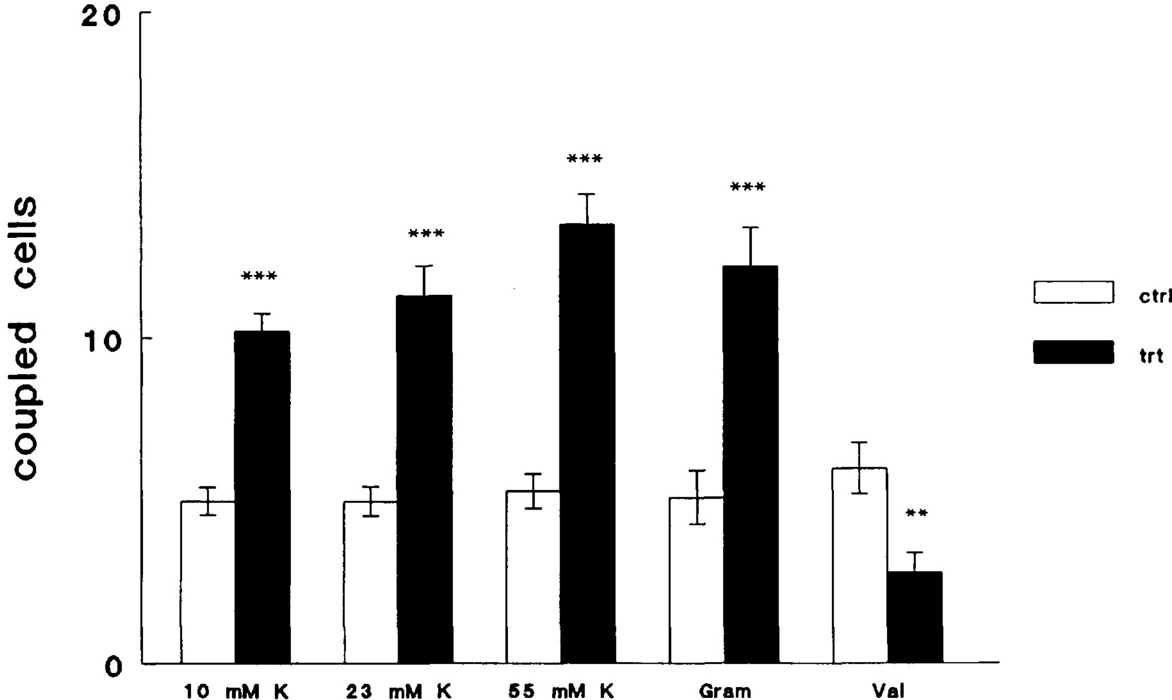

FIG. 23-6. Number of cells coupled to the cell initially injected with lucifer yellow dissolved in buffer containing 65 nM Ca^{2+}. Cells were incubated with the effectors for 10 minutes. Each treatment (*dark bars*) was preceded by injections on the same coverslip under control conditions (*white bars*). The three first treatments represent substitution of extracellular K^+ for Na^+ to 10, 23, and 55 mM K^+. The last two treatments were with ionophores; *Gram*, 2 μM gramicidin; *Val*, 2 μM valinomycin. Data from several coverslips were pooled and is presented ± SEM. *** $p < .001$, ** $p < .005$, Student's *t* test. *n* = 2, 3, 6, 3, 3 coverslips, respectively, with 10 cells injected for each treatment on one coverslip.

gest that astrocytes *in vivo* may influence the growth and differentiation of neurons. It is evident that the release of a number of these different neuroactive substances is controlled by neuroligand receptor activation. For example, work by many investigators make it clear that astroglia contain nerve growth factor (NGF) and that the release of NGF is stimulated by receptor agonists (Schwartz et al., 1977; Furukawa et al., 1987; Houlgatte et al., 1989; Schwartz and Mishler, 1990; Carman-Krzan et al., 1991; Rudge et al., 1992; Zafra et al., 1992). Enkephalin peptides (Melner et al., 1990; Batter et al., 1991), S-100 (Barger and Van Eldik, 1992), and taurine (Shain et al., 1986) also appear to be released by astroglia. As all type 1-like astroglia examined to date exhibit beta-adrenergic receptors, it seems that one role of these receptors may be to increase the release of these neuroactive substances in brain during development. Interestingly, beta-adrenergic receptor stimulation has been reported to open L-type Ca^{2+} channels via the activation of PKA (Bowman and Kimelberg, 1987), whereas stimulation of alpha$_1$-adrenergic receptors results in depolarization of astroglia (MacVicar and Tse, 1988). Overall, it is evident that astroglia exhibit a number of different signal transduction systems, which may influence the synthesis and release of neuroactive factors from astroglia. A major question yet to be resolved is the level to which astrocytes contribute to the release of neurotrophic factors in the adult brain. It remains possible, if not likely, that immature astrocytes contribute to the release of neurotrophic factors during development, while such factors are provided primarily by neurons in the adult brain. Ongoing research in a number of laboratories is aimed at this question.

The idea that astrocytes in brain supply neurons with metabolic nutrients (e.g., glucose) was raised by the early anatomists and is supported by a number of *in vitro* studies (Cummins et al., 1983; Rosenberg and Dichter, 1988; Pfeiffer et al., 1992; Sorg and Magistretti, 1992). In brain, glycogen appears to be located almost exclusively in astrocytes (Peters et al., 1976). Glycogen breakdown in astrocytes is stimulated by agents that increase either cyclic AMP or Ca^{2+} (Cummins et al., 1983; Krutsay, 1986; Sorg and Magistretti, 1991). Furthermore, it has been reported that glycogen phosphorylase (the rate-determining enzyme in glycogenolysis in brain) is restricted in brain to astrocytes (Pfeiffer et al., 1992). These findings

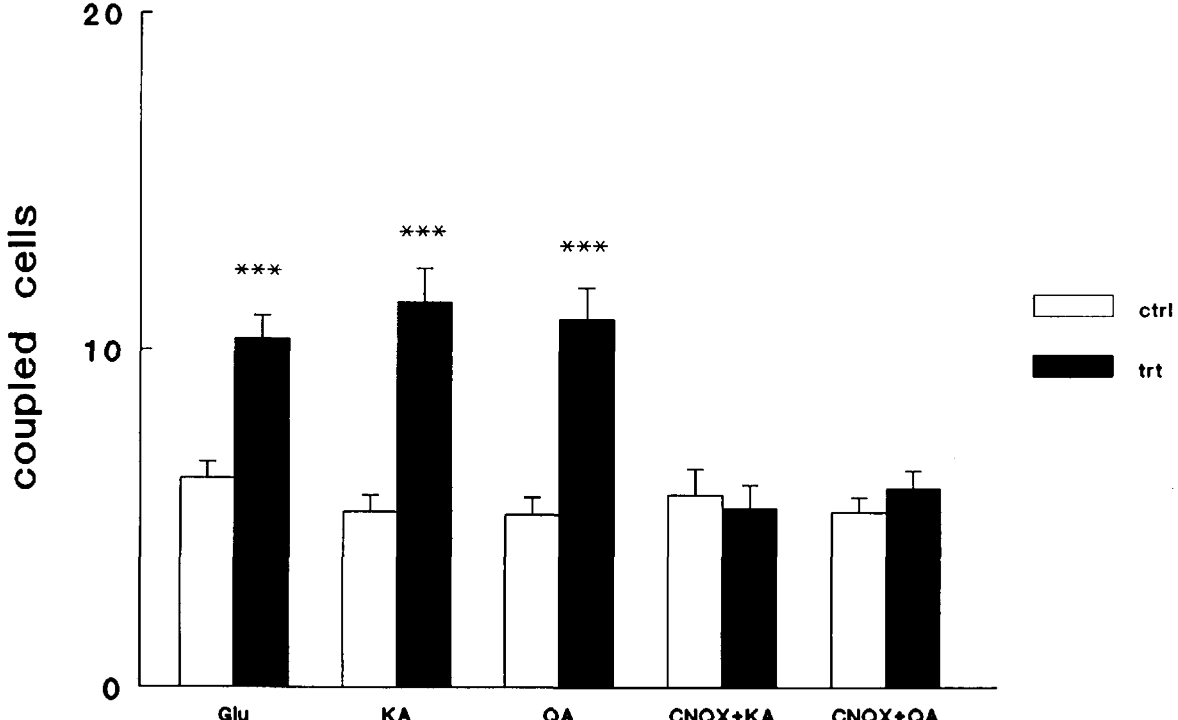

FIG. 23-7. Number of cells coupled to the cell initially injected with lucifer yellow dissolved in buffer containing 65 nM Ca^{2+}. Each treatment (*dark bars*, 10 injections per coverslip) was preceded by injections on the same coverslip in control buffer (*white bars*, 10 injections per coverslip). *Glu*, treatment with 400 μM glutamate for 20 min; *KA*, 400 μM kainate for 20 minutes; *QA*, 400 μM quisqualate for 20 minutes; CNQX+KA, CNQX+QA, treatment with 10 μM CNQX and 400 μM kainate or quisqualate; respectively, for 20 minutes. Data from several coverslips were pooled and is presented ± SEM. *** $p < 0.001$, Student's t test. n = 6, 4, 4, 3, 3 coverslips, respectively.

strongly suggest that in brain, astrocytes may respond to adrenergic receptor stimulation (either alpha- or beta-ARs) with the breakdown of glycogen and release of metabolic substrates to be utilized by neurons.

A number of investigators have reported that neuroligands that increase either PKA or PKC activity affect the morphology of astroglial cells *in vitro*. While the mechanism by which this occurs remains unclear (Pollenz and McCarthy, 1986), increasing the activity of either PKC or PKA converts astroglia from a flat, polygonally shaped cell to a process-bearing cell (Narumi et al., 1978; Mobley et al., 1986; Shain et al., 1987). The morphological conversion of these cells induced by increases in cyclic AMP frequently has been interpreted as reflecting an increase in the differentiation of astroglia. While this may be the case, it is difficult to argue given the absence of markers for mature astrocytes. A different view of the morphological change is that this process reflects the ability of astrocytes to change shape in response to exposure to neuroligands. Changes in astrocytic shape *in vivo* could affect neuronal excitability and synaptic activity by changing the volume of the extracellular space and/or neuronal connections. Changes in astrocytic morphology *in vivo* have been reported by investigators studying glia during lactation (Salm et al., 1985). Additional experiments will be required to determine whether changes in astrocytic morphology *in vivo* are a general property of these cells.

SUMMARY AND FUTURE DIRECTIONS

It is clear that astroglia *in vitro* and astrocytes *in vivo* exhibit adrenergic receptors. The role that these and other astroglial neuroligand receptors play in brain function is less evident. *In vitro* studies indicate that while all astroglia exhibit β-ARs, only a percentage of these cells exhibit α_1-ARs. The fact that astroglia are heterogeneous with respect to their expression of neuroligand receptors *in vitro* indicates that these receptor systems are not expressed in response to *in vitro* growth conditions. In contrast to our expectation, the expression of a given receptor system by astroglia changes over time such that cloned cells grown in an identical chemical and cellular environment become pharmacologically heterogeneous. These findings indicate that intrinsic

clocks persist in astroglia *in vitro* and determine their ability to respond to their local chemical milieu. Even more surprising was our demonstration that brief exposure to ligands that increase Ca_i^{2+} results in the loss of muscarinic cholinergic responses in astroglia. The loss of muscarinic sensitivity appears to be unique in that other cells examined failed to exhibit similar regulation. These findings suggest that astrocytes may undergo qualitative changes in their ability to respond to neuroligands and that these changes may be regulated by neuroligands released at specific times during development. Studies indicate that astroglial cells continue to express neuroligand receptors even when grown in direct contact with neurons and exhibiting a morphology different from astroglia growing a short distance away.

Overall, these findings suggest that the signal transduction systems of astrocytes *in vivo* may change during development in response to both intrinsic and extrinsic signals. By extension, the degree to which the activity of these cells is influenced by neuroligands released from neurons is likely to change during development. We hypothesize that during development immature astrocytes exhibit a large number of neuroligand receptors and that these are necessary to interact with a changing neuronal environment. With brain maturation, the number of neuroligand receptor systems expressed by astrocytes markedly decreases to a number dependent on the heterogeneity of the local neuronal environment. The role that astrocytic receptor systems play in mature brain remains elusive.

Results indicating that astroglia respond to neuroligands with an all-or-none rise in Ca_i^{2+}, which then moves through astroglia in a regenerative manner, are very reminiscent of neuronal action potentials. It seems likely that neuroligand-induced Ca_i^{2+} waves represent an extraneuronal signaling system that may serve to modulate neuronal activity. Modulation could occur through a number of processes, including changes in the ionic composition of the extracellular space, release of substances that would directly affect neuronal excitability, and the physical rearrangement of neuronal synapses.

The amount of information on astroglia that has accumulated during the past two decades is very impressive. However, of the many different properties that have been described using astroglia *in vitro,* few if any are known to be critical to normal brain function in the mature animal. To date, there is not a single example where the perturbation of an astrocytic property leads to a defined deficit in brain function. Indeed, it remains controversial whether astroglia *in vitro* reflect the properties of immature, mature or pathological astrocytes. To establish the importance of astrocytes in brain function, it will be necessary to develop methods that can be used to study these cells *in vivo.* It is clear that the development and use of these methods will be difficult and sometimes less definitive. However, if gliobiologists are to convince the scientific community that astrocytes are major players in brain function, these cells must be studied *in vivo.* In addition to characterizing the properties of these cells *in situ,* it will be necessary to perturb these properties *in vivo* in order to demonstrate their importance in brain function. While certainly more difficult than using culture systems, the sophisticated electrophysiological and molecular biological approaches being applied in neurobiology should lead to major conceptual advances in our understanding of astrocytes *in vivo.*

24 Peptide receptors on astrocytes

GRAHAM P. WILKIN, DEREK R. MARRIOTT, AND BRIAN PEARCE

It is now abundantly clear that astrocytes can express a multiplicity of cell surface receptors rivaling that of neurons. They are able to respond to amino acids, amines, peptides, purines, and prostaglandins. Unlike neurons, however, astrocytes are not connected synaptically, and thus any neuroactive molecules reaching them following release into the synaptic cleft must do so secondarily. Many different types of peptides have been shown to be present presynaptically where they are stored in large, dense-core vesicles. They tend to be present at lower concentrations than the classical neurotransmitters and are probably released at higher frequencies of stimulation (Scheller and Hall, 1992). There is still uncertainty about the mechanism and sites of their release within the presynaptic bouton. Further, whereas the amino acids and amine neurotransmitters are rapidly removed from the synaptic and other extracellular spaces by high-affinity uptake transporters in both neurons and astrocytes, peptides appear to be degraded extracellularly and persist longer than the amino acids or amines. Thus they can both act over longer periods of time and possibly diffuse further than the classical neurotransmitters (Scheller and Hall, 1992). Peptides released from one neuron might well activate receptors on several local glial cells. In addition to neuronally released peptides, other synthetic compartments may also be important. Astrocytes themselves have been shown to be immunoreactive for angiotensin II (Stornetta et al., 1988; Intebi et al., 1990), endothelin (Ehrenreich et al., 1991), preproenkephalin (Vilijn et al., 1988; Shinoda et al., 1989), somatostatin (Shinoda et al., 1989), and substance P (Michel et al., 1986; Kostyk et al., 1989) and thus may release peptides to act in an autocrine or paracrine fashion. Following damage to the central nervous system (CNS) and breakdown of the blood brain barrier (BBB), both blood-borne peptides and those originating in cells of the immune system may also be of importance.

Most of the data that are available so far on glial peptide receptors, have been obtained from experiments using cultured astrocytes. These cells have been usually obtained from neonatal animals and both their developmental and reactive status in culture is unclear. It is important, therefore, to correlate receptor expression in culture with expression *in vivo*. These correlations are beginning to be made, and they will be noted here. Of necessity, in the space available, we have been able to give only a slim overview of a rapidly expanding field of research. We have had to be selective in our choice of representative references and apologize to the authors of many that we have not included.

We first reviewed data about peptide receptors in 1988 (see Wilkin and Cholewinski, 1988). As far as we are aware there has been no further information forthcoming on the effects of calcitonin, corticotropins, glucagon, melanocyte-stimulating hormone, or parathyrin since that time, so readers of this chapter are referred to the previous review for information about those peptides.

ANGIOTENSIN II

The octapeptide angiotensin II (AII) is synthesized both in peripheral tissues and in the CNS. The activation of AII receptors in the circumventricular organs of the brain seems to be responsible for the regulation of blood pressure and water and sodium balance. These receptors respond both to blood-borne and cerebrospinal fluid-derived AII (Ganong, 1983). In addition to the circumventricular receptors, both neurons and astroglia in other brain regions have been found to express AII receptors (Sumners et al., 1990). The physiological function of these receptors is, however, less clear.

The central nervous system possesses an intrinsic renin-angiotensinogen-angiotensin 1-converting enzyme system (RAS) necessary for the synthesis of the peptide (Ganong, 1983). Components of the RAS have been found in both neurons and astrocytes (Kumar et al., 1988; Raizada et al., 1984; Sumners and Raizada, 1984), although recently the latter cell type has become more the focus of attention. Astrocytes appear to possess a full complement of essential components for the synthesis and degradation of AII. Indeed, studies by Intebi et al. (1990) and Stornetta et al. (1988) using both astrocyte cultures and

in situ hybridization showed that astrocytes seem to be the major synthetic compartment for angiotensinogen. Further, Intebi et al. (1990) demonstrated that astrocytes from subcortical regions produced more peptide than cortical ones, a finding consistent with both the *in vivo* distribution of the peptide and the regional heterogeneity of astrocytes (see Wilkin et al., 1990, for references pertaining to heterogeneity). Intebi et al. (1990) go so far as to suggest that astrocytes may even supply angiotensinogen to neurons for further processing.

AII receptors have been divided into two major types: AT_1 and AT_2. This designation was made possible by the availability of AII antagonists such as DuP753 and PD123177, which block AT_1- and AT_2-linked responses, respectively (see Sumners et al., 1991). AT_1 receptor cDNA clones were isolated from both rat (Iwai et al., 1991; Murphy et al. 1991) and bovine (Sasaki et al., 1991) tissues, and subsequently a second form of the AT_1 receptor has been described which was isolated from the rat anterior pituitary (Kakar et al., 1992). AT_{1a} and AT_{1b} receptors display 95% homology. Both astrocytes and neurons possess AII receptors (Sumners et al., 1990). Pharmacological studies have revealed that rat astrocytes possess receptors of the AT_1 subtype (Bottari et al., 1992), while human astrocytes (derived from neoplastic brain) additionally express AT_2 receptors (Jaiswal et al., 1991). Whether the AT_1 receptors are of the subtype a or b awaits analysis, using the newly described molecular probes. In contrast to astrocytes, Sumners et al. (1991) reported that neurons cultured from whole-rat brain expressed predominantly AT_2 receptors, with a lesser number of AT_1s. AT_{1a} and AT_{1b} receptors are differentially expressed in the CNS. Whereas AT_{1a} mRNA is expressed predominantly in the hypothalamus and the median eminence, the cerebellum, subfornical organ, and organum vasculosum of the lamina terminalis have more AT_{1b} mRNA. In contrast, the area postrema had approximately equal quantities of AT_1 subtypes (Kakar et al., 1992). mRNA expression was found to be in good agreement with the presence of AT_1 receptors determined by radiolabeled ligand binding receptor assays and quantitative autoradiography (see Kakar et al., 1992 for references). However, the regional disposition of the particular cell types, astrocytes or neurons, bearing AII receptors has yet to be determined.

Several functional consequences of AII receptor activation have been reported. Sumners et al. (1991) demonstrated that AT_1 receptors on rat astrocytes derived from whole brain were coupled to increased phosphatidylinositol (PI) turnover, whereas neuronal receptors predominantly of the AT_2 type were linked to a reduction of basal cGMP levels. Human astrocytes displayed both AT_1 and AT_2 linked prostaglandin release (Tallant et al., 1991). Whereas the AT_1 receptors were linked to Ca^{2+} mobilization, the AT_2 receptors were not, suggesting that the latter receptors stimulated arachidonic acid mobilization and prostaglandin release through a Ca^{2+} independent mechanism.

A further intriguing function of the AT_1 receptor is its coupling to the release of plasminogen activator inhibitor 1 (PAT-1) from astrocytes derived from 21-day-old rats (Olson et al., 1991; Rydzewski et al., 1992). Astrocytes derived from neonatal animals did not display this response, suggesting that the response may be developmentally regulated. Stimulation with 10 nM AII led maximally to a 20-fold increase in PAI-1 mRNA and release of the protein into the culture medium. The function of the released PAI-1 is at present uncertain, but Rydewski et al. (1992) speculate that it may provide a way of regulating AII action in the brain.

BRADYKININ

Bradykinin (BK) is a nine-amino acid peptide deriving from a precursor, kininogen, following the action of a serine protease, kallikrein. The general interest in this peptide results from the fact that BK is a mediator of pain, inflammation, and hypotension (Dray and Perkins, 1993). It is synthesized in peripheral tissues and in the CNS. The latter appears to have its own endogenous capacity for BK synthesis. Both kininogen and kallikrein have been detected in the brain and BK itself has been localized immunocytochemically and measured quantitatively by radioimmunoassay (Correa et al., 1979; Perry and Snyder, 1984; Kariya et al., 1985). Although these latter quantitative data indicated that the peptide was present in many regions of the rat brain, albeit at relatively low concentrations, recent autoradiographic studies of guinea pig brain showed that binding sites for ^{125}I-BK were restricted to the medulla oblongata (Privitera et al., 1991). Other studies on the regional distribution of ^{3}H-BK binding to membranes of guinea pig brain suggested a wider distribution of receptors and appear to be at odds with the studies of Privitera et al. (Sharif and Whiting, 1991). Further studies should shed more light on these anomalies.

Which CNS cell types are capable of responding to BK? Responses have been reported in brain cortical and thalamic neurons (Phillis and Limacher, 1974; Davis and Dostrovsky, 1988). Cultured rat brain neurons were shown to possess receptors for

^{125}I-BK (Lewis et al., 1985), and cultured rat brain endothelial cells responded to BK with changes in intracellular Ca^{2+} levels (Revest et al., 1991). We found that astrocytes derived from the cortex, cerebellum, and spinal cord (and, more recently, optic nerve and corpus callosum: D. Marriott and G. Wilkin, unpublished observations) of neonatal rat all responded to BK with increased rates of phosphatidylinositol turnover (Cholewinski et al., 1988). Binding studies on the cortical cells with ^{3}H-BK revealed high-affinity binding sites of just one affinity displaying saturability and reversibility (Cholewinski et al., 1991). BK receptors were initially subdivided into types 1 and 2 on the basis of their interactions with a number of antagonists. Using two of these, Des-Arg^{9},[Leu^{8}]-BK (BK-1 antagonist) and D-Arg[Hyp^{3}-,D-Phe^{7}]-BK (BK-2 antagonist) we determined the receptors on astrocytes to be of the BK-2 type (Cholewinski et al., 1991). The rat BK_2 receptor has recently been cloned and sequenced, revealing a predicted structure homologous to the seven transmembrane G protein-coupled superfamily of receptors (McEachern et al., 1991). Now that this information is available, construction of suitable probes for *in situ* hybridization should enable the location of BK receptor-bearing cells to be specified in the CNS.

Binding of BK to astroglial receptors results in several consequences, the induction of a membrane current, the elevation of internal Ca^{2+} and the release of prostaglandins (Gimpl et al., 1992; Wilkin and Marriott, 1993).

ENDOTHELINS

First described in 1988 (Yanagisawa et al.), the endothelin family comprises three 21-amino acid peptides (endothelins 1-3, ET-1-3). All three possess intrachain disulfide bridges, which are also found in the snake sarafotoxins (for review see Greenberg et al., 1992). ET-1 is the most potent vasopressor yet found, causing sustained elevation of blood pressure through its action on smooth muscle cells. The three endothelins, coded for by three separate genes, have been demonstrated in the genomes of human, rat, and pig (Inoue et al., 1989). Although endothelins are present in the human nervous system (Giaid et al., 1989; Lee et al., 1990) the subtype(s) have not yet been defined. Both ET-1 and ET-3 are, however, found in the brains of experimental animals (Matsumoto et al., 1989; Shinmi et al., 1989). In the human CNS, ET mRNA and ET-like immunoreactivity are localized in endothelial cells and neurons (Giaid et al., 1989; Lee et al., 1990). Other reports suggest that astrocytes are also capable of synthesizing endothelins. MacCumber et al. (1990) presented evidence for the expression of mRNA for ET-1 by cultured rat cerebellar astrocytes, although, in contrast, Hama and colleagues (1992) failed to demonstrate its presence. Ehrenreich et al. (1991), however, found that astrocytes from neonatal rat brain displayed ET-3-like immunoreactivity and released the peptide into the culture medium. With respect to endothelial cell synthesis of endothelins, Yoshimoto et al. (1991) found that cerebral microvessel endothelium is capable of producing ET, whereas Vigne et al. (1990) found that they did not. Clearly, much work remains to be done before a full picture of the synthetic compartments for the synthesis of ETs in the CNS is obtained.

cDNA clones for ET receptors have been isolated through the use of direct expression techniques (see Sakurai et al., 1992). Although pharmacological studies have suggested that there may be a number of receptor subtypes (see Gulati and Srimal, 1992, for references), Southern blot analysis of human, pig, and rat genomic DNA has revealed only two distinct genes (Sakamoto et al., 1991). The receptors coded for by these genes have been dubbed ET_A and ET_B. The former is selective for ET-1, whereas the latter displays equipotent affinity for all three ETs and sarafotoxin. An outstanding question is which CNS cell types express which receptor? Autoradiographic studies have shown that binding sites for ETs are found throughout the CNS (Kohzuki et al., 1991). However, the resolution of such studies is such that it is not possible to localize receptors to individual cell types, and therefore, analysis of cultured cells have been undertaken. Hösli and Hösli (1991) demonstrated autoradiographically that both neurons and astrocytes derived from cerebellum and spinal cord expressed binding sites for ^{125}I-ET-1 and 3, and the growing literature suggests that, indeed, both cell types respond to ETs (see references in Gulati and Srimal, 1992).

Hama et al. (1992) demonstrated that ETs act on astrocytes through the ET_B receptor. They found that ET reversed the effects of dibutyryl cAMP by stimulating cell division and suppressing glutamine synthetase activity. ET-induced mitosis has also been demonstrated by Suppatapone et al. (1990) and MacCumber et al. (1990). Several studies have shown that cultured astrocytes respond to ETs with increased phosphatidylinositol turnover and calcium flux (MacCumber et al., 1990; Marsault et al., 1990; Lin et al., 1990; Holzwarth et al., 1992; Morton and Davenport, 1992). One consequence at least of these intracellular messenger changes has been reported to be an inhibition of gap junction permeability

(Giaume et al., 1992). Since their discovery in 1988, there has clearly been a great deal of interest in the ETs; however, much remains to be done, and at this time, it appears that astrocytes may well turn out to be an important functional compartment in the CNS.

NATRIURETIC PEPTIDES

Natriuretic peptides comprise a family of molecules 21-33 amino acids in length. Atrial natriuretic peptide (ANP), the first to be discovered (de Bold et al., 1985), is a peptide of some 28 amino acids. In the brain N-terminally shortened forms exist, a-ANP (4-28) and a-ANP (5-28) (Ueda et al., 1987). Brain also contains two further members of the family, brain natriuretic peptide (BNP) and C-type natriuretic peptide (CNP) comprising 26 amino acids and 22 amino acids, respectively (Sudoh et al., 1988; Sudoh et al., 1990). In contrast to ANP and BNP, which are concentrated in the heart, CNP is found in high concentrations in the CNS (Ueda et al., 1991). BNP immunoreactivity is more widely distributed throughout the rat brain than is ANP, and is found in all regions of the cerebral cortex and in the amygdala, cerebellum, circumventricular organs and area postrema, hippocampus, and olfactory bulb (Saper et al., 1989). Likewise, CNP is distributed throughout the brain and spinal cord, with particularly high concentrations in the cerebellum, medulla, pons, and hypothalamus (Ueda et al., 1991). Although most earlier studies suggested a neuronal location for natriuretic peptides, recently two reports have appeared demonstrating the presence of ANP in astrocytes. McKenzie (1992) found ANP-like immunoreactivity in astroglia throughout the canine brain. The number of positive cells per unit area of section was usually small, with the exception, however, of a group of cells in one hemisphere. McKenzie suggested that these data might indicate that astroglia express ANP only transiently, perhaps in response to local perturbation, and the small group of ANP-positive cells was the result of such a environmental change. However, a tissue culture study in which all the cells would have been exposed to the same conditions, also showed that only a small number of astrocytes were ANP-immunoreactive (Schipper et al., 1991).

Cloning and sequencing of natriuretic peptide receptors has revealed three separate types, designated GC-A, GC-B, GC-C, and ANPCR. The first three not only act as receptors for peptides, but when activated also synthesize cGMP by virtue of their intracellular catalytic domains. GC-C, however, appears to be a receptor for a bacterial enterotoxin rather than a natriuretic peptide. The fourth receptor does not contain a guanylyl cyclase domain and appears to act as an ANP clearance receptor (for review see Garbers, 1992). Autoradiographic studies of ANP receptors have revealed their presence in various regions of the brain, predominantly, however, in the subfornical organ and other regions without a blood-brain barrier (Kurihara et al., 1987). Within the area postrema of the circumventricular organs, Konrad et al. (1992) demonstrated that ^{125}I-ANP bound to both neuronal processes and astrocytes. In contrast a study by Vente et al. (1990) suggested that astrocytes are the major target for ANP. These workers located ANP-stimulated cGMP immunohistochemically in the olfactory bulb, amygdala, and hippocampus, and in each region the responsive cells were astrocytes. Several studies have also shown that cultured astrocytes respond to natriuretic peptides with increases in cGMP (Friedl et al., 1985; Simmonet et al., 1989; Beaumont and Tan, 1990). A recent study by Yeung et al. (1992) showed that, of the three natriuretic peptides described so far, CNP was the most effective in stimulating cGMP production. As yet, the functional consequences of this increase in cGMP levels within astrocytes are unknown.

OPIOIDS

The interactions of opioid peptides with astrocytes have been studied using cells cultured from cerebral and cerebellar cortices and pituicytes from the posterior pituitary. The actions of opioid peptides and opiate agonists on astrocytes appear to be inhibitory. Both Rougon et al. (1983) and Eriksson et al. (1990) found that opioid receptor agonists antagonized rises in cAMP induced through other receptor types. Pearce et al. (1985) demonstrated that opioid receptors were responsible for the attenuation of an adrenergic-stimulated increase in 2-[^{14}C]deoxyglucose incorporation into glycogen. In a series of studies, Stiene-Martin and Hauser (1990, 1991; Stiene-Martin et al., 1991) demonstrated that opioid receptors are linked to the inhibition of cell division in astrocytes. The receptor types that seem to be important in these phenomena are delta and kappa, rather than those of the mu subclass. All of these receptor types are present in the CNS early in development (Ruis et al., 1991), and the studies of Stiene-Martin and Hauser might suggest that it is during development that opioid actions on astrocytes are of the greatest importance. However, in adulthood, kappa opioid receptors do appear to be

present on a specialized subset of astrocytes, the pituicytes, both in the normal posterior pituitary and following lesion of the neuronal innervation (Bunn et al., 1985). The physiological function of kappa receptor activation is unclear. It has been proposed that pituicytes, through changes in their position relative to oxytocin- and vasopressin-containing terminals, may have a role to play in hormone release (for a recent review see Hatton, 1990). However, while beta-adrenergic ligands induced pituicyte movements both in the isolated gland and in presumptive cultured pituicytes, the kappa ligand dynorphin was without effect (Bicknell et al., 1989; Luckman and Bicknell, 1990). More recent data from this laboratory, however, indicate that dynorphin both delays and reduces vasopressin-induced calcium movements in presumptive cultured pituicytes (R. Bicknell, personal communication). We have used the term *presumptive* with respect to cultured pituicytes in the experiments described above, as their phenotype in culture is debated (Bunn et al., 1990). Burnard et al. (1991) have demonstrated dynorphin-activated electrophysiological changes in pituicytes in isolated rat pituitaries.

OXYTOCIN AND VASOPRESSIN

The two classical neurohormones oxytocin and vasopressin, readily associated in most minds with the hypothalamus, are found in axons that project from this region to the posterior pituitary. Projections to other parts of the CNS have also been mapped (Zimmerman, 1983). In a comparative study of three CNS regions we demonstrated a heterogeneity in the response of astrocytes in respect of phosphatidylinositol turnover (Cholewinski et al., 1988). In each region both peptides gave the same response. The greatest increase was seen in cortical astrocytes (about 150% over basal) followed by cerebellar astrocytes (about 70% over basal) with negligible responses in spinal cord cells. Recent studies by Di Scala-Guenot and Strosser (1992) have characterized the oxytocin receptors on cultured astrocytes from rat hypothalamus and hippocampus. They used an iodinated selective oxytocin antagonist to demonstrate that the receptors were different from those previously reported for neuronal cultures. Few studies have been carried out to examine the possible functions of receptor activation. Del Bigio et al. (1992) found that vasopressin caused a mild swelling of mouse astroglia, and Hatten et al. (1992) demonstrated that vasopressin mobilizes intracellular Ca^{2+} in cultured rat pituicytes, while Hösli et al. (1991) reported membrane depolarization of rat spinal cord and brainstem astrocytes.

SOMATOSTATIN

Somatostatin, comprising 14 amino acids, was initially isolated from the hypothalamus and has been found to act both as an inhibitor of hormone release and as a central neurotransmitter. In the CNS the distribution of the peptide and its receptor is widespread and exhibits regional, quantitative variations (Pelletier et al., 1986; Fitzpatrick-McElligott et al., 1991). Until recently, however, the cellular targets for centrally released somatostatin were completely unclear. A degree of clarification has now been achieved through the use of gold-conjugated somatostatin that retains its binding characteristics. Mentlein et al. (1990) and Krisch et al. (1991) undertook studies of both cultured cells and brain slices to microscopically locate the binding sites for this ligand. In both cases astrocytes featured prominently as a compartment to which somatostatin bound. Not all astrocytes in either the cultures or sections were labeled, but, importantly, in the sections there was a general correlation between the distribution of somatostatin-immunoreactive terminals and the pattern of peptide binding. This suggests that not only are astrocytes regionally heterogeneous with respect to their possession of somatostatin receptors, but they are also located correctly to respond to locally released peptide. A report from Kluxen et al. (1992) suggests that the somatostatin receptor has now been cloned, raising the possibility of *in situ* hybridization studies as another approach to locating receptor-expressing cells.

As stated above, somatostatin generally acts in an inhibitory manner, and its action on astrocytes is no exception. Several studies have shown that it has no effect on basal cAMP levels, but is an effective inhibitor of stimulated increases in this second messenger brought about by a number of different agonists (see Wilkin and Cholewinski, 1988, for references). Beyond these changes in cAMP levels, however, the functional significance of somatostatin effects on astrocytes is unknown.

SUBSTANCE P

Substance P (SP) is an 11-amino acid member of the tachykinin family, which also includes neurokinins A and B (Maggio, 1988). Both the peptide and its

receptors are found throughout the CNS (Helke et al., 1990). Several tachykinin receptors have been cloned and their sequences indicate that they belong to the ever-growing seven transmembrane G protein-linked family (Masu et al., 1987; Yokota et al., 1989; Shigemoto et al., 1990). A great deal of interest has been taken in SP ever since the suggestion of a function in pain pathways, in particular in the dorsal horn of the spinal cord (Jessell, 1983). In comparative studies of the effects of SP on astrocytes derived from neonatal rat cortex, cerebellum, and spinal cord, the latter cells were unique in that they were the only ones to respond to SP with increased phosphatidylinositol turnover (Cholewinski et al., 1988). Subsequently, this heterogeneity was confirmed by Beaujouan et al. (1990) who measured ^{125}I-SP binding sites and found substantial numbers on astrocytes derived from rat brainstem or spinal cord, but low or negligible binding on other CNS-derived cells. In contrast to the data obtained on rat astrocytes, Torrens et al. (1986) had found that murine astrocytes from several CNS regions all possessed high-affinity SP binding sites functionally linked to phosphatidylinositol turnover. These sites have now been shown to be coupled to Ca^{2+} fluxes (Delumeau et al., 1991). Although the reason for this difference between two closely related species is not understood, recent experiments undertaken in our laboratory have revealed the reason for the regional variation in rat brain astrocyte responses to SP. It turns out that the cell types that respond best to SP are the type 2 astrocyte and its precursor the O-2A cell, which derives from white matter tracts (Marriott and Wilkin, 1993). It appears that type 1 astrocytes have very low numbers of receptors, but presumably even low numbers would be enough to invoke the type of membrane changes in K^+ and Cl^- channel opening reported by Backus et al. (1991).

The correlation between SP responsiveness and white matter is intriguing in the light of data from Mantyh et al. (1989), who showed that SP receptors appeared in gliotic lesioned rabbit optic nerve. This appears to be a phenomenon associated with myelinated tracts as Mantyh and Hunt (1986) had previously shown no such upregulation of SP receptors in lesioned gray matter. We now have to determine the cell type responsible for the new expression of SP receptors in damaged optic nerve, but our *in vitro* data suggest that the type 2 astrocyte is a candidate. A consequence of the activation of SP receptors is the release of prostaglandins (Hartung et al., 1988; Marriott et al., 1991) which might be of considerable importance in inflammatory response following white matter damage.

THYROTROPIN RELEASING HORMONE

Although the highest concentration of the tripeptide thyroptropin releasing hormone (TRH) is found in the hypothalamus, quantitatively, more than 70% of total CNS TRH is found outside this region (Reichlin, 1986). The distribution of receptors for this peptide is also widespread throughout the CNS (Manaker et al., 1985). TRH and its dimethylated analogue, RX 77368, have been used in trials to treat patients with motoneuron disease with reported relief of some symptoms (Modares-Sadeghi and Guiloff, 1990). As a part of a study in rats to examine target cells for TRH, we measured its effects on cultured astrocytes derived from neonatal rat cortex, cerebellum, and spinal cord (McDermott et al., 1992). We found relatively modest, but significant, increases in phosphatidylinositol turnover, in all three regions, with the largest increases in the cerebellum. While the regional variations were supportive of astrocyte heterogeneity (Wilkin et al., 1990), the functional significance of the presence of TRH receptors on astrocytes is unknown.

VASOACTIVE INTESTINAL PEPTIDE

Vasoactive intestinal peptide (VIP) is a large peptide of some 28 amino acids first described in 1970 by Said and Mutt. Both VIP and its receptors, mapped using the iodinated molecule, are found throughout the central nervous system (Loren et al., 1979; Martin et al., 1987). The cerebral cortex possesses high levels of both peptide and receptor, and has an interesting population of VIP-positive radially oriented interneurons suggested by Magistretti (1986) to play a role in local glycogenolysis. Although a general picture of the distribution of peptide and receptors is clear, the cell-specific location of receptors is not, prompting a recent study by Martin et al. (1992). They compared the receptor characteristics of astrocytes, microvessels, and synaptosomal membranes from mouse cortex. All three expressed high-affinity binding sites for ^{125}I-VIP, with the neuronal sites differentiated from the nonneuronal ones by the finding that the related peptide, secretin, competed with only the neuronal sites.

Studies in several laboratories have shown that activation of VIP receptors on astrocytes leads to increases in cAMP levels (see Wilkin and Cholewinski, 1988). In a comparative study of rat astrocytes from cortex, cerebellum, and spinal cord we found that by far the greatest response was elicited in the cortical cells, which interestingly parallels the high level of the peptide in this brain region (Cholewinski and Wilkin,

1988; Loren et al., 1979). If the *in vitro* data reflect the *in vivo* situation, then we might predict that cortical astrocytes in the brain will be shown to express sufficient numbers of VIP receptors to enable them to respond effectively to local neurons. Downstream of cAMP synthesis VIP promotes glycogenolysis both in cultured astrocytes (Sorg and Magistretti, 1991) and in cerebral cortical slices (Schaad et al., 1989) suggesting a function for the peptide in the local regulation of energy metabolism. Other astrocytic functions have also been determined by Brenneman and colleagues (1990) who demonstrated that VIP is a secretagogue for a neuron survival-promoting activity and also a mitogen for cultured astrocytes.

CONCLUSIONS

Clearly, astrocytes now have to be seriously considered as potential targets for neuropeptides. It is necessary for the time being to continue to use the word potential, because most of the data derive from studies on cultured cells. Nonetheless, the results of Krisch et al. (1991) and Mentlein et al. (1990) on somatostatin receptor labeling and the dynorphin-induced physiological responses of pituicytes of Burnard et al. (1991) point the way forward. It is now important to investigate the localization of astrocyte peptide receptors within the substance of the CNS proper. We look forward to understanding the relationships between astrocyte receptor expression and local neuronal populations both during development and in the adult, and the changes that may result from reactive gliosis. Undoubtedly, further receptor cloning and the raising of novel antibodies to the various receptors will have a considerable bearing on our progress.

25 Eicosanoid, purine, and hormone receptors

BRIAN PEARCE AND GRAHAM P. WILKIN

Research into glial cell receptors has focused mainly on characterizing receptors for the major classes of signal molecules released from neurons: amines, amino acids and peptides. However, these cells also appear to express receptors for a variety of other substances that may not be solely derived from neurons. Among these are the purines and eicosanoids, agents that might be released from sources such as other glia, neurons, or cells of the vasculature. Although we are far from fully understanding the roles played by these agents in the central nervous system (CNS), involvement in inflammatory and immune responses and regulation of the vasculature are prime candidates. Glia are also targets for steroid hormones, thyroid hormones, insulin, and insulin-like growth factors. Some of these may be synthesized locally, while others may enter the CNS from the circulation. As a general rule, the site of action of these hormones is the nucleus, the responses they regulate being primarily long-term events, such as cell growth, differentiation, and metabolism.

The aim of this chapter is to summarize the evidence for the presence of receptors for this diverse group of signal molecules on glia. This will be derived predominantly from studies of cultured cells; however, attention will be drawn to studies on *in situ* glia. We will also consider the transduction mechanisms coupled to these receptors and the downstream consequences of receptor activation.

EICOSANOID RECEPTORS

All eicosanoids are synthesized from a common precursor, arachidonic acid, via a sequence of enzymatic reactions along either the cyclooxygenase or lipoxygenase pathways to yield prostaglandins (PGs) and leukotrienes, respectively. It has been known for some time that eicosanoids are synthesized within the CNS and are likely to be involved in mediating a variety of cellular events (Wolfe, 1982; Chiu and Richardson, 1985). Studies on cultured cells have suggested that glia and astrocytes in particular may be a major source of eicosanoids in the brain (Murphy et al., 1988). Glia are also targets for these agents, indicating that eicosanoids may be involved in both paracrine and autocrine functions.

Early indications for the presence of eicosanoid receptors on glia came from studies on whole brain cultures and clonal cell lines. In their review of 1980, van Calker and Hamprecht outlined experiments showing that PGE_1, -E_2, and -I (prostacyclin) were capable of activating adenylate cyclase and increasing intracellular cyclic adenosine monophosphate (AMP) concentrations, whereas PGA_1, -A_2, -B_1, -$F_{1\alpha}$, and -$F_{2\alpha}$ were all without effect. With the advent of techniques to produce cultures enriched in either astrocytes or oligodendrocytes, McCarthy and de Vellis (1980) reported that both cell types responded to PGE_1 with an increase in cyclic AMP but that this effect was much greater in oligodendrocyte-enriched cultures. More recent studies have shown that some PGs act on receptors coupled to phosphoinositide breakdown and intracellular Ca^{2+} mobilization.

Both thromboxane A_2 (TXA_2) and $PGF_{2\alpha}$ have been found to promote inositol phospholipid metabolism in cultured cells. Nakahata et al. (1989, 1992) demonstrated the presence of a single, high-affinity binding site for TXA_2 on both human 1321N1 astrocytoma and primary cultures of adult rabbit cerebral cortex. Stimulation of these receptors with a stable TXA_2 analogue resulted in the accumulation of intracellular inositol phosphates in both cell types (Nakahata et al., 1989, 1992). Similarly, Kitanaka et al. (1991) found that $PGF_{2\alpha}$ stimulated phosphoinositide breakdown in rat cortical astrocytes. The receptors for TXA_2 and $PGF_{2\alpha}$ appear to be coupled to phospholipase C, the enzyme responsible for catalyzing phosphoinositide metabolism, via a regulatory G protein which is not sensitive to pertussis toxin (Kitanaka et al., 1991; Nakahata et al., 1989, 1992).

Interestingly, $PGF_{2\alpha}$-evoked phosphoinositide breakdown can be modified by prior treatment of cultures with dibutyryl cyclic AMP. This is a well-established method of transforming protoplasmic astrocytes into cells with a stellate morphology. Under

these conditions $PGF_{2\alpha}$-stimulated inositol phosphate accumulation was enhanced in cortical, hippocampal, and particularly cerebellar astrocyte cultures (Kitanaka and Baba, 1992). Whether this reflects an increase in PG receptor number or is a function of cell differentiation is unclear. However, differences in PG-evoked responses have recently been noted in cultures enriched in protoplasmic and stellate astrocytes prepared from newborn rat cerebral cortex. In both cell populations PGE_1 and $-E_2$ were found to increase intracellular cyclic AMP levels, but the responses were much greater in cells with a stellate morphology (Ito et al., 1992). Apparently, these differential effects were not due to varying adenylate cyclase activities because forskolin, a direct activator of this enzyme, caused similar responses in both cell types. Ito et al. (1992) also examined changes in intracellular Ca^{2+} concentration in cells loaded with the fluorescent indicator fura-2AM (see Chapter 17, this volume). When challenged with $PGF_{2\alpha}$, $-D_2$ and a TXA_2 analogue, only protoplasmic astrocytes responded with an increase in internal Ca^{2+}, an effect that was insensitive to pertussis toxin. Even though stellate astrocytes were unresponsive to these eicosanoids, internal Ca^{2+} could be mobilized by other agents, such as histamine (Ito et al., 1992).

As previously mentioned, eicosanoids are synthesized from arachidonic acid, a constituent of many membrane phospholipids. There is increasing evidence that arachidonic acid itself may serve as a signal molecule; indeed, Murphy and Welk (1989) have shown that it stimulates phosphoinositide breakdown in cortical astrocytes (see Chapter 34, this volume). This effect was found not to be secondary to arachidonic acid metabolism, nor was it the result of its insertion into the membrane; the suggestion was that its action may be receptor-mediated.

Despite the evidence for the presence of eicosanoid receptors on glia in culture, there are few indications of either their functions or whether they exist on cells *in situ*. McCarthy et al. (1985) have shown that at least one of the downstream consequences of PGE_1 receptor activation in astrocytes is the phosphorylation, presumably via a cyclic AMP-dependent protein kinase, of the intermediate filament proteins glial fibrillary acidic protein (GFAP) and vimentin. One might therefore suggest that certain eicosanoid receptors may be involved in cytoskeletal organization during astrocyte differentiation. In addition, Sawada et al. (1993) reported that endogenously synthesized prostanoids regulate astrocyte proliferation. Whether these receptors serve a similar function in oligodendrocytes remains to be determined. Another area still to be fully explored is whether glia possess receptors for leukotrienes. We know that astrocytes are capable of synthesizing these agents (Hartung and Toyka, 1987), but, to our knowledge, there is no evidence for the existence of their receptors on these cells.

PURINE RECEPTORS

Extensive pharmacological characterization of purinergic receptors has led to them being classified as either P_1 or P_2 purinoceptors. P_1 receptors are activated by adenosine and can be further subdivided into A_1 and A_2 receptors on the basis of various functional criteria. A_2 receptors are positively coupled to adenylate cyclase, whereas A_1 receptors have been shown to be either negatively linked to adenylate cyclase or coupled to phosphoinositide breakdown. P_2 purinoceptors recognize adenosine triphosphate (ATP) and can also be divided into various subtypes. The P_{2X}, P_{2Y}, P_{2T}, and P_{2Z} purinoceptors can be distinguished according to agonist selectivity, the cell types possessing receptors and the response initiated upon stimulation.

P_1 *Purinoceptors*

Several lines of evidence point to there being P_1 purinoceptors of both A_1 and A_2 subtypes on glia. Receptors have been identified autoradiographically in explant cultures of rat cerebellum and spinal cord (Hösli and Hösli, 1988) and agonist-induced decreases (A_1) and increases (A_2) in cyclic AMP formation have been observed in a number of primary culture preparations (van Calker and Hamprecht, 1980; Barnes and Thampy, 1982; Ebersolt et al., 1983). The work of McCarthy and de Vellis (1980), however, suggests that the A_2 receptor subtype may be located predominantly on astrocytes.

Recently, attention has focused on glial A_1 receptors. In striatal and mesencephalic, but not cortical, astrocytes, 2-chloroadenosine, a stable adenosine analogue, was found to potentiate α_1-adrenoceptor-induced phosphoinositide metabolism without having activity itself (El-Etr et al., 1989). Delumeau et al. (1991) found that a combined addition of A_1 and α_1-adrenergic agonists to striatal astrocytes produced a sustained increase in intracellular Ca^{2+} concentration, this response being far greater than that caused when the agonists were used separately. Part of this change in internal Ca^{2+} appeared to be due to the receptor-stimulated influx of extracellular Ca^{2+} (Delumeau et al., 1991). These authors have suggested that A_1 receptors are coupled, via a pertussis toxin-sensitive G protein, to phospholipase A_2 and that their actions on phosphoinositide metabolism and Ca^{2+} flux are indirect, being mediated by

A_1 receptor-evoked arachidonic acid liberation (El-Etr et al., 1992).

Researchers have examined some of the functional correlates of P_1 purinoceptor activation in cultured glia. In common with other agents that elevate intracellular cyclic AMP in these cells, adenosine has been shown to promote GFAP and vimentin phosphorylation (McCarthy et al., 1985) and glycogen breakdown (Magistretti et al., 1983) in astrocytes presumably via the activation of the A_2 receptor subtype. Hösli et al. (1987) reported that glia in explant cultures were hyperpolarized by adenosine. The receptor subtype involved in this response is not known, but an ability to modulate membrane K^+ ion conductance seems likely.

P_2 Purinoceptors

The first indication that extracellular ATP had an effect on glia came from the work of Trams (1974). In clonal cell lines ATP was found to alter membrane permeability to various ions, an effect attributed to its action on membrane-bound ectoenzymes. It is now clear, however, that glia possess specific receptors for ATP. In cultured cortical astrocytes ATP induces the breakdown of phosphoinositides via its interaction with P_2 purinoceptors (Pearce et al., 1989). Subsequent studies have concentrated on receptor-mediated intracellular Ca^{2+} mobilization in these cells. Using fura-2AM-loaded astrocytes, it has been shown that approximately 50 to 60% of both protoplasmic and stellate cortical astrocytes respond to ATP with an increase in cytosolic Ca^{2+} concentration, an effect mediated by the P_{2Y} class of receptors (Dave et al., 1991; McCarthy and Salm, 1991; Kastritsis et al., 1992). This response was characterized by a rapid, transient release of stored Ca^{2+}, followed by a more sustained influx of extracellular Ca^{2+} (Kastritsis et al., 1992). The dependence of this part of the response on extracellular Ca^{2+} tends to confirm the earlier work of Neary et al. (1988), who found that ATP promoted radiolabeled Ca^{2+} uptake into these cells. Although the evidence for P_{2Y} purinoceptors coupled to phosphoinositide metabolism is quite strong, electrophysiological studies suggest that glia may possess a subset of P_2 receptors that are linked to membrane ion channels. ATP has been shown to depolarize cultured microglia (Kettenmann et al., 1993) and astrocytes (Magoski and Walz, 1992). This phenomenon has been best characterized in astrocytes where ion substitution experiments revealed that this response was mediated by changes in Na^+ and K^+ flux and the use of various agonists showed a pharmacological profile that does not correspond to any of the accepted P_2 purinoceptor subtypes (Magoski and Walz, 1992).

Functional correlates of P_2 purinoceptor activation have been confined to studies on astrocytes where they appear to be involved in regulating protein phosphorylation and eicosanoid release. Neary et al. (1991) reported that the phosphorylation patterns of four specific proteins were altered in astrocytes challenged with ATP. Two of these proteins, one of which was identified as GFAP, showed enhanced phosphorylation, while in two others phosphorylation was reduced. Thus, P_2 purinoceptors appear to be involved in modulating the activity of Ca^{2+}-dependent protein kinases and phosphatases. With regard to eicosanoid release, ATP has been found to stimulate the release of PGD_2 (Gebicke-Haerter et al., 1988) and TXA_2 (Pearce et al., 1989) from rat cortical astrocytes and TXA_2 from human glioma (Murphy et al., 1990). Bruner and Murphy (1990) have shown that arachidonic acid liberation, and by implication eicosanoid release, is mediated by P_{2Y} purinoceptors, which corresponds to the findings on phosphoinositide metabolism and Ca^{2+} mobilization discussed earlier. However, there is evidence to suggest that eicosanoid release may not be entirely dependent upon ATP-stimulated phosphoinositide breakdown but may involve either the direct coupling of receptors to phospholipase A_2 and/or the activation of a membrane Ca^{2+} channel (Seregi et al., 1992; Bruner and Murphy, 1993).

THYROID HORMONE RECEPTORS

The important role played by thyroid hormones during brain development is well established (Grave, 1977). It is perhaps not surprising, therefore, that these hormones are involved in regulating various aspects of glial maturation. Indeed, it has been shown that thyroid function can markedly influence the development of glial cells in the intact brain (Clos et al., 1980; Pesetsky, 1983).

The action of thyroid hormones is believed to be due to the binding of triiodothyronine (T_3) to receptors in the nucleus of target cells and ligand binding studies have established the presence of T_3 receptors in nuclear fractions prepared from cultured glia (Luo et al., 1986; Puymirat and Faivre-Bauman, 1986). Using a monoclonal antibody raised against rat liver T_3 receptors, Luo et al. (1989) have shown immunocytochemically the localization of T_3 receptors in the nuclei of both protoplasmic and stellate astrocytes prepared from newborn rat cerebral cortex. Most of the cells in these cultures were labeled; however, the receptors appeared more slowly over time

in culture in protoplasmic astrocytes compared to those with a stellate morphology.

The consequences of T_3 receptor activation strongly support a role for these receptors in regulating glial differentiation. Various aspects of myelin production are stimulated by T_3 in oligodendrocyte cultures (Shanker et al., 1985; Koper et al., 1986). In addition, the activity of the astrocyte marker enzyme glutamine synthetase (GS) is influenced by treatment with thyroid hormone, as is the transformation of astrocytes from a protoplasmic to a stellate form (Aizenman and de Vellis, 1987).

STEROID HORMONE RECEPTORS

The brain contains receptors for both adrenocorticoids and those hormones (progestins, estrogens, androgens) usually associated with reproductive functions (McEwan et al., 1982). These receptors are molecularly similar to those found in non-neural tissues and appear to be involved in the regulation of CNS development and behavior.

Androgen, Progesterone, and Estrogen Receptors

Cultured glia, particularly oligodendrocytes, are known to be capable of synthesizing steroids such as pregnenelone and progesterone (Jung-Testas et al., 1989). These authors have also presented evidence for the presence of receptors for these hormones on cultured cells. In cultures containing both oligodendrocytes and astrocytes, Jung-Testas et al. (1991) demonstrated specific binding of ligands to estrogen (ER), androgen (AR), and progesterone (PR) receptors. Estimates of the number of receptor sites per cell indicated that the ER were the predominant species, being almost twofold greater in number than either the AR or PR. Further studies revealed that the number of PR, but not AR or ER, in these cultures could be markedly increased by prior treatment of the cells with estradiol (E_2). Jung-Testas et al. (1991) also showed that staining with an antibody against the PR was confined to the inner nuclear membrane and occurred primarily in oligodendrocytes. These findings were essentially confirmed in a later paper by this group in which cultures enriched in either astrocytes or oligodendrocytes were used. Astrocytes were found to possess very few PRs; moreover, those that were present appeared to be confined to cells derived from female animals and could not be increased in number by E_2 treatment (Jung-Testas et al., 1992). In contrast, oligodendrocytes prepared from both male and female animals possessed PRs and, although more abundant in cultures from females, receptors in cells from both sexes were increased by exposure to E_2 (Jung-Testas et al., 1992).

Functional studies suggest that these steroid hormone receptors play a role in glial cell development. Garcia-Segura et al. (1989) showed that E_2 induced hippocampal astrocytes to adopt a stellate morphology. In addition, treatment of mixed glial cultures with either E_2 or progesterone resulted in changes in the expression of GFAP and myelin basic protein (MBP), these responses being particularly evident in immature cultures (Jung-Testas et al., 1992). Interestingly, Torres-Aleman et al. (1992) have recently shown that the E_2-induced differentiation of hippocampal astrocytes can only occur when the cells are in contact with neurons.

In recent years, our view of steroid hormone receptors being in the cytoplasm and/or nucleus of cells, and the effect of the hormone being mediated via mRNA synthesis and protein expression, has changed. Evidence now suggests that steroid hormones can also elicit rapid nongenomic effects via interactions with membrane-bound receptors. Various metabolites of progesterone and deoxycorticosterone are capable of influencing the activity of both inhibitory and excitatory amino acid receptors in the CNS (Paul and Purdy, 1992). Probably the best studied are those steroids that bind to a site associated with the $GABA_A$-Cl^- ion channel receptor complex. It has been known for some time that cultured glia possess $GABA_A$ receptors (Kettenmann et al., 1988; see Chapter 21, this volume). Recently, Chvatal and Kettenmann (1991) have shown that GABA-mediated membrane currents in cultured cortical astrocytes can be both positively and negatively modified by steroids in a manner similar to their actions on neurons. The functional implications of these effects, however, remain to be elucidated.

The question of whether glia *in situ* possess steroid receptors is open to debate. Autoradiographic and *in situ* hybridization studies indicate that AR and ER do not exist on glia in adult rat brain (Keefe et al., 1991). However, glia in the intact CNS do seem able to respond to both the administration of these hormones and the manipulation of their levels in living animals. For example, the administration of E_2 to adult female rats and the alteration of neonatal levels of estrogens and androgens in male and female rats caused changes in astrocyte morphology and GFAP expression in various brain regions (Garcia-Segura et al., 1986, 1988). These authors have suggested that glial responses to sex hormones may be important in determining synaptic remodeling and the sexual differentiation of the brain.

Adrenocorticoid Receptors

Adrenocorticosteroids activate two classes of intracellular receptor, the mineralocorticoid (MR) or type I receptor and the glucocorticoid (GR) or type II receptor. These receptor classes can be distinguished on the basis that the MR displays a higher affinity for corticosterone than does the GR, which preferentially binds synthetic glucocorticoids such as dexamethasone (Ruel and de Kloet, 1985). There is abundant evidence that cultured glia possess both types of receptor and that they are involved in mediating a variety of cellular events.

Ligand binding studies on cultured glia point to the existence of a single population of GRs in both astrocytes and oligodendrocytes (Chou et al., 1991; Kumar and de Vellis, 1988). These receptors appear to be located in the cytoplasm, but, as immunocytochemical studies have shown, they migrate to the nucleus in the presence of a receptor ligand (Bohn et al., 1991). Chou et al. (1991) have also reported that MRs are present in astrocytes. Similar binding studies have not been carried out on purified oligodendrocyte cultures; however, Bohn et al. (1991) have confirmed the presence of MRs in these cells using antibody labeling.

Nothing is known of the role played by MR in glia; however, the functional correlates of GR stimulation are well documented. Glucocorticoids are known to modulate the expression of a variety of glial proteins, for example, the expression of GS and MBP, and glycerol phosphate dehydrogenase is enhanced in cultured cells (Kumar and de Vellis, 1988). Warringa et al. (1987) have suggested that GR activation may be involved in determining whether bipotential glial precursor cells develop into either astrocytes or oligodendrocytes.

Evidence for the presence of these receptors in glia *in situ* is mainly indirect, although low levels of GR mRNA have been detected in white matter cells (Aronsson et al., 1988). It is clear, however, that glia in the intact brain can respond to glucocorticoids. Adrenalectomy results in increased myelination (Meyer and Fairman, 1985), while glucocorticoid administration inhibits myelination (Gumbinas et al., 1973), the genesis of oligodendrocytes (Bohn and Friedrich, 1982), and the expression of GFAP (O'Callaghan et al., 1989).

INSULIN AND INSULIN-LIKE GROWTH FACTOR RECEPTORS

Insulin and the insulin-like growth factors (IGF) I and II are structurally related molecules. The IGFs are synthesized within the brain, but it is not entirely clear whether the same is true for insulin (Masters et al., 1989); nonetheless, receptors for all of these substances have been found in various central nervous system regions (Gammeltoft et al., 1984; Masters et al., 1989). We are still some way from fully understanding the roles these agents play in the central nervous system, although it is generally accepted that they are likely to be involved in regulating cellular development and metabolism (see Chapter 32, this volume).

Probably the first demonstration of glial insulin receptors came from binding studies on astrocyte-enriched fractions prepared from adult rat brain (Albrecht et al., 1982). Subsequently, a number of workers have reported similar findings from experiments performed on cultured astrocytes (Kum et al., 1987; Clarke et al., 1988). Astrocyte insulin receptors are similar to their neuronal and liver counterparts in that they possess an α and β subunit; however, these subunits have molecular weights intermediate between the neuronal and peripheral receptor types probably because of differences in attached carbohydrate moeties (Clarke et al., 1988). Despite these differences, astrocyte insulin receptors appear to have similar requirements for the structure of the ligands they bind, particularly in relation to the C terminus of the B chain of the insulin molecule (Zhu et al., 1990). Having outlined these studies, it should be noted that Han et al. (1987) found only low levels of specific insulin binding to cortical astrocytes. They did, however, find binding sites for IGF-I and IGF-II on these cells; moreover, autoradiography revealed that these receptors are membrane-bound, but are subsequently internalized and migrate toward the nucleus (Han et al., 1987). Masters et al. (1991a) and McMorris et al. (1986) have shown that IGF receptors are also present on oligodendrocytes and bipotential precursor cells.

There is a considerable body of evidence pointing to insulin and the IGFs being glial mitogens. Insulin, IGF-I, and IGF-II have all been reported to promote precursor incorporation into DNA or to increase cell numbers in glial cultures (McMorris et al., 1986; Ballotti et al., 1987; Han et al., 1987; Kum et al., 1987; Shemer et al., 1987; Clarke et al., 1988; Masters et al., 1991a). In those studies where ligand potencies have been established, it would appear that IGF-I receptors are probably responsible for controlling glial proliferation. Insulin may also be involved in regulating glial differentiation, although reports in the literature are sometimes contradictory. For example, it has been shown that insulin is capable of influencing the phenotypic appearance of astrocytes and the expression of mRNA for GFAP

and its encoded protein in cerebellar organotypic cultures (Toran-Allerand et al., 1991). In contrast, Aizenman and de Vellis (1987) found that insulin had no effect on astrocyte morphology in primary cultures. These authors also reported that insulin and hydrocortisone were synergistic in their ability to induce GS expression in rat cortical astrocytes (Aizenman and de Vellis, 1987); however, Tholey et al. (1986) demonstrated the exact opposite in embryonic chick brain astrocytes. Whether this discrepancy is due to the different species of animal used or its developmental stage is not clear.

In peripheral tissues, insulin is well known to be involved in regulating cell metabolism. Studies on cultured cells suggest that glial glucose utilization may be similarly controlled by insulin and IGFs. Insulin at low nanomolar concentrations stimulates the uptake of glucose into astrocytes (Clarke et al., 1988) and its subsequent incorporation into glycogen (Dringen and Hamprecht, 1992; Kum et al., 1992). Shemer et al. (1987) suggested that glucose uptake may be a function of insulin rather than IGF-I receptor activation. However, Dringen and Hamprecht (1992) have shown that IGF-I is more potent than insulin in inducing glycogen formation in astrocytes. This metabolic response may, however, be developmentally regulated because Masters et al. (1991b) reported that IGF-I only activates the glucose transporter in cultures prepared from newborn animals; in cultures of adult tissue, IGF-I was found to be ineffective.

The intracellular transduction mechanisms linked to insulin and IGF receptors have yet to be fully characterized. There is evidence that these receptors may be coupled to a tyrosine kinase; indeed, insulin- and IGF-evoked kinase activation has been demonstrated in cultured glia (Clarke et al., 1988; Masters et al., 1989). However, this is unlikely to be the only signaling pathway operated by these molecules. Roles for protein kinase C and an as yet unidentified cytosolic factor that is involved in the activation of a regulatory ribosomal protein have also been suggested (Masters et al., 1989).

CONCLUSIONS

The list of receptors known to be present on cultured glial cells is growing steadily. We are beginning to characterize the signal transduction pathways coupled to these receptors and the biological consequences of receptor activation. As always, however, we are faced with the question: do these receptors exist on glia in the intact brain? In some cases it is probable that they are expressed in *in situ* glia, particularly receptors for certain hormones, insulin and/or IGF, and so on, where their presence may be developmentally regulated and involved in glial maturation and differentiation. Whether this is also true for purine and eicosanoid receptors is still open to debate. Although the evidence points to these agents serving as signal molecules in the CNS, it remains to be established whether glia in the normal brain are targets for them. It is conceivable that the expression of these receptors in cultured cells is telling us something about the status and possible functions of glia in the damaged brain. The removal of glia from their connections with neurons, other glia, the vasculature, and so on, and into the culture dish, might be an approximation of the situation they face during inflammatory conditions or vascular insults. This raises the interesting and as yet unanswered question of whether glia express certain types of receptors in response to changes in their physical and/or chemical environment.

V Mechanisms of Cell-to-Cell Communication

This page intentionally left blank

26 Extracellular space as the pathway for neuron-glial cell interaction

CHARLES NICHOLSON

This chapter will deal with current concepts of the extracellular space, how it can be defined in terms of a small number of biophysical parameters, and how these parameters enable us to explore the migration of substances between neurons and glia. The question of length scale will be discussed using a simple general model based on recent analyses of diffusion in the brain and a model applicable to very short-range interaction based on axon-Schwann cell interaction. An overview of the spatial-buffering hypothesis for potassium will be presented as an example of a mechanism where glial cells are thought to play a major role.

EXTRACELLULAR SPACE AND THE PARAMETERS THAT DEFINE IT

It is now appreciated that the space between cells of the brain is not simply an empty region separating membranes, but a complex environment that likely plays an important role in many processes that occur in the brain. The term *brain extracellular microenvironment* (BEM) will be used here, designating the environment encountered by a molecule when that molecule is in the space between cells of the brain. A similar term *brain cell microenvironment* was coined by Schmitt and Samson in a workshop as far back as 1969. In the intervening years it has become necessary to distinguish the extracellular from the intracellular microenvironment so that the term BEM is now more appropriate. Further information on this topic can be found in Nicholson (1980), Schmitt (1984), and Cserr (1986).

The idea of nonsynaptic communication between cells (Nicholson 1979) has been discussed most recently under the name of volume transmission (Fuxe and Agnati, 1991) and nonsynaptic diffusion neurotransmission (Bach-y-Rita, 1993). Numerous papers have provided evidence for the transmission of chemical signals between glia and neurons (a few randomly chosen recent examples: Stone and Ariano, 1989; Butt, 1991; Evans et al., 1991; Grimaldi et al., 1991; Grossfield et al., 1991; Lierberman, 1991; Martin, 1992; Lieberman et al., 1993). In Chapter 31 in this book, Orkand discusses aspects of this issue at greater length. The purpose of this chapter is to consider what constraints the biophysical properties of the extracellular microenvironment impose on the movement of substances between cells.

Volume Fraction, Tortuosity, and Uptake

A useful way to think of the extracellular space, in the words of Kuffler and Potter (1964), is that "... these spaces ... in three dimensions ... resemble the water phase of a foam." This is illustrated in Figure 26-1A. A substance released from a neuron or glial cell enters a restricted space where it is hindered in its diffusion by the presence of numerous cell membranes; finally, the substance may be actively taken up and modified or metabolized at some of the membrane surfaces.

It is now clear that the fraction of brain volume that is extracellular space amounts to 20% of the total brain volume. This rather large value arises because every area of cellular membrane is associated with an "atmosphere" of extracellular space so that the immense amount of cellular membrane per unit volume in brain tissue leads naturally to an appreciable volume.

While volume fraction is an important determinant of the distribution of substances in the BEM, it is not the only one. A somewhat less intuitive, but equally important parameter is tortuosity. This parameter measures the extent to which the cellular obstructions of the brain hinder the movement of substances. For a long time studies concentrated on either volume fraction or tortuosity but did not determine both, or in some cases even failed to recognize them as separate entities (for further discussion see Nicholson and Phillips, 1981).

Both volume fraction and tortuosity are morphological parameters and, in ideal measurements, are

independent of the substance or method used to measure them. A third, substance-specific, aspect of the BEM is the uptake property or the extent to which a given substance is removed from the extracellular space. Because of the high membrane:extracellular volume ratio in the BEM a certain amount of nonspecific loss of any substance occurs, and this generally is linearly related to extracellular concentration. In many cases, however, material is actively transported across membranes by an energy-dependent uptake system that obeys nonlinear kinetics or the substance may be metabolized *in situ*.

These three factors—volume fraction, tortuosity and uptake—determine how far substances will move in the extracellular space and so have the potential to play a major role in glia-neuronal interaction.

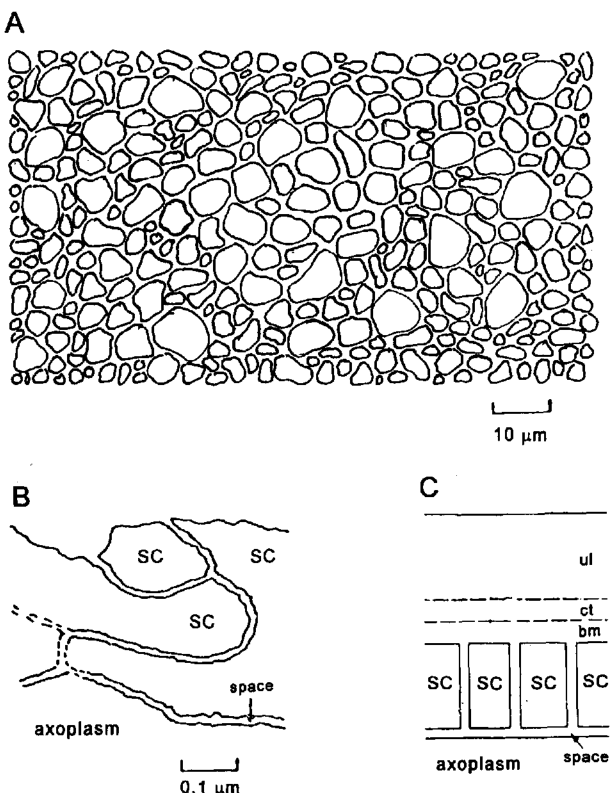

FIG. 26-1. Geometry of the extracellular space at different length scales. (A) Geometry appropriate for a scale of greater than 1 μm. The closed profiles represent cell bodies, dendrites, glial processes, and axons. The space between cells resembles the liquid phase of a foam. Substances are released into a restricted volume, defined by the volume fraction α and hindered in their movement through the brain by cellular obstructions, which constitute a tortuosity factor, λ. In addition, uptake or degradation of molecules occurs at membrane surfaces. (B) Relationship between a giant axon and surrounding Schwann cells. Models based on this geometry seek to account for behavior of substances in the space between the axon and immediate Schwann cells (*SC*) and are applicable on a length scale of less than 1 μm. In this model the primary route for escape of substances from the space was envisaged to be the clefts between cells. (C) A later representation of the geometry shown in Figure B. The Schwann cells are now represented by rectangular cells separated by regular clefs. Beyond these lie a basement membrane (*bm*), connective tissue (*ct*) and an unstirred layer (*ul*). See text for further details. [Figure B modified from Frankenhaeuser and Hodgkin (1956), with permission; Figure C modified from Taylor et al. (1980), with permission.]

Spatial Scale and Diffusion

In discussing neuron-glia interaction it is important to consider the spatial scale involved. When distances of tens of micrometers are considered, the morphological parameters are subsumed into the three factors described in the preceding section (Figure 26-1A). On the other hand, some questions revolve around the interaction of a neuron with its surrounding glial sheath. In axon-Schwann cell interactions, for example (Figures 26-1B,C), local morphology will play the dominant role. The diffusion of substances over varying distance scales is differently affected by the geometry of the BEM and by uptake processes.

As an example of this interaction, to be described below, glial cells have a special mechanism for removing the K^+ released by neurons from the BEM. Over short distances the movement of K^+ is mainly limited by diffusion but over long distance a novel form of uptake known as spatial buffering comes into play and both these processes are subject to further modulation by active transport of the K^+ by either neurons or glia.

Dynamic Aspects

The facets of the BEM briefly mentioned above show great potential for dynamic behavior. The net movement of solutes across membranes leads inexorably to water movement and with it changes in cell volume and alterations in the architecture of the extracellular space (e.g., Nicholson, 1980; Dietzel et al., 1989). Such changes may be of functional importance or they may play a major role in pathophysiology. In a real sense the whole structure of the BEM, and indeed the brain itself, is a dynamic entity that is sustained by the continuous consumption of energy. This behavior may be modulated by neuroactive factors. A discussion of the role of glia in glucose metabolism is presented in Chapter 52. Our emerging picture of the BEM is that of a dynamic entity whose properties can change with time, and the presumption is that glia play a role in this behavior.

VOLUME FRACTION

The volume fraction of the BEM is defined as α, the ratio of the extracellular phase of brain tissue to the total tissue phase (which comprises extracellular phase, intracellular phase, and boundary or membrane phase) of a small volume of brain tissue. The volume fraction is therefore a dimensionless ratio.

It was not always believed that the percentage volume fraction of the BEM was 20%, indeed early estimates, based on electron microscopy suggested that it was no more than 5% (Horstmann and Meves, 1959). Other methods of estimating the percentage volume at that time, such as impedance and radiotracer measurements with Na^+ or Cl^-, gave very variable results so that the true percentage was a matter of debate for a number of years. One of the earliest investigators to accurately estimate the percentage volume was van Harreveld (1972), who used a variety of techniques, including electron microscopic methods, that attempted to preserve the spaces between cells.

Consistent estimates of extracellular volume fraction, as it has come to be known, became available with the use of careful quantitative radiotracer methods based on molecules that remained extracellular. Thus Levin et al. (1970), using labeled sucrose and inulin, obtained values of 18 to 20% in the cerebral cortex of four mammalian species. Most recently, the local iontophoresis of TMA^+ and an analysis of its diffusion characteristics have provided accurate measurements in the living brain (Table 26-1). This method provides sufficient temporal resolution that changes in volume fraction can be followed in real time.

One possible reason why the volume fraction cannot be negligible is because it has to act as a conduit, between blood vessel or ventricular surface and cell surface, for metabolic substrates and waste products. When the brain is subjected to anoxic insult, the extracellular volume fraction decreases (van Harreveld, 1972; Lundbæk and Hansen, 1992; Syková et al., 1994), due presumably to the swelling of cells but never totally occludes, even during ischemic conditions where it reaches a minimum volume of about 5%.

It is also striking (see Table 26-1) that the volume fraction is preserved across species. Thus similar values are reported in fish, reptiles, and mammals. Even more impressive is that similar values can be seen in cephalopod invertebrates. Cephalopods are represented by the octopus, squid, and cuttlefish and have sufficient brain mass to permit measurements of α. Both radiotracer studies (Abbott et al., 1985) and TMA^+ studies (Nicholson et al., 1995) have shown that α is comparable to vertebrates in at least some regions.

The basic similarities in α make the exceptions interesting. Thus, in the rat hippocampus it was reported (McBain et al., 1990) that the volume fraction of CA1 was only 0.12 and the vertical lobe of the cuttlefish may have a similar low value (Nicholson et al., 1995); both these reductions in α may reflect local structural properties. Rice et al. (1993) have recently shown that in the cerebellar molecular layer, when anisotropy is accounted for, the volume fraction reaches 0.31. Previous studies of this region did not

	Vertical lobe	0.10	1.65	Nicholson et al., 1995

[a]These cerebellar measurements in the molecular layer did not take anisotropy into account.

take the anisotropy into account, which is led to errors in estimating α. Indirect evidence from impedance measurements in the retina (Karwoski et al., 1985) suggests that α is 0.12 in the subretinal space and 0.11 in the inner and outer plexiform layers, but only 0.03 in the outer and inner nuclear layers and 0.02 in the ganglion cell and optic nerve fiber layers.

Knowing the volume fraction does not tell us how close the membranes of cells are to each other. Conventional wisdom has it that the spaces are about 15 to 20 nm in width (Schmitt and Samson, 1969), but very recent studies based on the optical imaging of a graded series of fluorescent dextrans indicate that the spaces are larger than 5 nm. A maximum size cannot be given at this time, but there are probably spaces of graded size; however, there are likely some regions less than 15 nm in width because molecules of this diameter are more hindered than smaller entities (Nicholson and Tao, 1993; see next section). Some morphologists (e.g., Bondareff and Pysh, 1968) have also suggested that the spaces between cells are not uniform but may enlarge into "lakes."

TORTUOSITY

Tortuosity defines the hindrance imposed by obstructions in the extracellular space. It was recognized in a number of earlier studies (e.g., Harris and Burn, 1948; Patlak and Fenstermacher, 1975) but only measured systematically with the advent of the TMA method. Because of this hindrance we refer to an *apparent* diffusion coefficient, D^*, in tissue. We can then define a factor, λ, the tortuosity, which accounts for the hindrance to extracellular diffusion that arises from the obstructions presented by cell membranes. Then tortuosity is conventionally defined by $\lambda = (D/D^*)^{1/2}$, where D is the diffusion coefficient in a free medium. Generally speaking (see Table 26-1), the tortuosity is about 1.6 so that $D^* \approx 0.4 \times D$. This implies a significant reduction in the ability of substances to move in the extracellular space compared to movement in a free solution.

Studies of the cerebellum have recently shown (Rice et al., 1993) that the molecular layer is anisotropic so that there are three values of λ (λ is a tensor), each associated with one of the three axes defined by the geometry. Diffusion is least hindered along the parallel fibers (x-axis) and in the direction normal to the surface (z-axis), but in the axis parallel to the surface and at right angles to the parallel fibers (y-axis), greater obstruction is encountered. The values of tortuosity (Table 26-1) are in the ratios: λ_x: λ_y: λ_z = 1.44:1.95:1.58. In practice this means that a substance released into the BEM of the molecular layer spreads out with an ellipsoidal pattern rather than in the shape of a sphere, so that there is a tendency for preferential spread along the parallel fibers. It may be anticipated that this trend would also be seen in white matter tracts where anisotropic impedance has been measured (Ranck and BeMent, 1965). These data also clarify the diversity seen in previous measurements of cerebellar parameters (Nicholson and Phillips, 1981, Houndsgaard and Nicholson, 1983, Nicholson and Rice, 1986), which were probably due to different orientations of the measuring axes with respect to the cerebellar axes. No such anisotropy is seen in the granular layer of the cerebellum, but the tortuosity is higher than average (Rice et al., 1993) (Table 26-1), presumably due to the dense packing of the tiny granule cells.

Recent studies using optical imaging methods (Nicholson and Tao, 1993) have enabled the study of the diffusion of fluorescent dextrans having molecular weights in the tens of thousands in contrast to the studies with TMA^+, which has a molecular weight of 74.1. These studies (Figure 26-2), on the rat neocortex, have revealed that up to a molecular weight of 10,000, the large molecules are no more hindered than TMA^+, but 40,000 and 70,000 MW dextrans demonstrate a significant increase in tortuosity. These data suggest that, although molecules

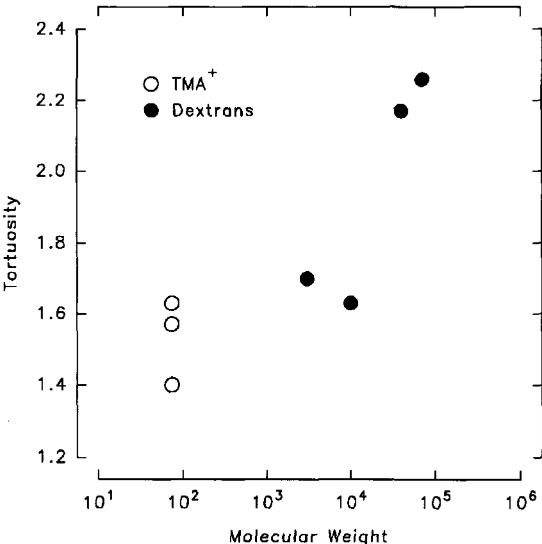

FIG. 26-2. Distribution of tortuosities measured with molecules of different molecular weights in the neocortex of the rat. Abscissa is molecular weight on a logarithmic scale, ordinate is tortuosity. Measurements made with TMA^+ (*open circles*) with molecular weight 74.1 and dextrans with molecular weights 3000 and 10,000 all lie between 1.4 and 1.7. The two largest dextrans of 40,000 and 70,000, however, show tortuosities exceeding 2.0. This suggests that such large molecules are excluded from some regions of the brain extracellular microenvironment.

above a certain size can still diffuse through the BEM, when the molecular weight reaches a value between 10,000 and 40,000 they are excluded from some regions. This is particularly significant, since many diffusible factors of current interest, such as nerve growth factor or its subunits, lie in the range of 26,000 to 130,000 MW (Thoenen and Barde, 1980).

Tortuosity could also reflect constraints that are not strictly geometrical, such as charge interaction with the long-chain tethered proteoglycans and glycosaminoglycans that are found in the extracellular space (Nicholson, 1980; Margolis et al., 1986; Iwata and Carlson, 1993) but so far no clear evidence of charge discrimination has been found (Nicholson and Phillips, 1981, Nicholson and Rice, 1987).

MODEL OF DIFFUSION OVER EXTENDED DISTANCES

The most basic process for the movement of substances through the extracellular space is diffusion, indeed, diffusion is an inescapable component of any transport process. It is also through the analysis of diffusion that volume fraction and tortuosity may be better appreciated. The model described below applies over distance scales of 1 μm or more; in the next section a model for a much shorter scale will be discussed.

A molecule, characterized by a free diffusion coefficient D ($cm^2 \cdot s^{-1}$) in aqueous solution, distributes in the BEM according to a generalization (Nicholson and Phillips, 1981; Nicholson, 1992) of the classic diffusion equation (see Carslaw and Jaeger, 1959 or Crank, 1975 for an extensive treatment of the diffusion equation):

$$\frac{\partial C}{\partial t} = \frac{D}{\lambda^2} \nabla^2 C + \frac{Q}{\alpha} - \frac{F(C)}{\alpha}. \tag{1}$$

The generalization introduces the two nondimensional factors, λ, the tortuosity, and α, the volume fraction, that incorporate the structure of the tissue, as described above. In a free aqueous medium $\alpha = 1$ and $\lambda = 1$, while in brain $\alpha < 1$ and $\lambda > 1$. Time (s) is denoted by t, while ∇^2 represents the second spatial derivative and C is the concentration (mM $\equiv$ $mmole \cdot L^{-1}$) of the diffusing molecules. A source-term Q ($mM \cdot s^{-1}$) describes local release of molecules. Uptake of material from the extracellular space, typically into cells, is defined by $F(C)$ ($mM \cdot s^{-1}$). If this function is zero or a linear function of C then Equation (1) can be solved for a variety of cases (Nicholson, 1992).

Diffusion from a Spherical Cell

To illustrate some of the implication of Equation (1), the equation can be simplified to represent the steady-state diffusion from a spherical cell of radius a. In this problem there are no sources distributed in the tissue, but instead we assume a substance being released across the cell membrane at a constant rate. This substance is generated in the cell at a rate of q μmoles per unit volume per second ($\mu M \cdot s^{-1}$) This means that the total amount leaving the cell is (*cell volume*) $\times$ q per unit time. The substance is removed throughout the BEM with a constant uptake ν ($\mu M \cdot s^{-1}$). This type of uptake is saturable, nonlinear, and an extreme example of Michaelis-Menten kinetics. Equation (1) becomes

$$\frac{D}{\lambda^2 r^2} \frac{d}{dr}\left(r^2 \frac{dC}{dr}\right) - \frac{\nu}{\alpha} = 0, \tag{2}$$

where r is the distance (cm) from the center of the cell and $r \geq a$.

The solution to this problem is more complex (Nicholson, 1995) than it appears at first sight, but intuitively it is clear that near the cell the uptake system is likely to be overwhelmed by the efflux of substance; since the rate of removal is fixed, this means that the uptake saturates. With further distance from the cell, the concentration drops due both to the uptake process and the divergence of the substance as it spreads out in three-dimensional space. As this happens the effectiveness of the uptake increases, and there is accelerated removal of the substance. It is fairly obvious that at some finite and calculable distance, b, all the substance will have been removed. This distance can be shown to be

$$b = a\left(1 + \frac{q}{\nu}\right)^{1/3}. \tag{3}$$

Note that this distance does not depend on the diffusion characteristics of the BEM, it is only a function of the rates of release and uptake per unit volume and the size of the cell. The concentration profile does depend on D, λ, and α and is expressed by

$$C = \frac{\lambda^2}{\alpha D} \frac{\nu}{6} \frac{b^3}{r}\left[\left(\frac{r}{b}\right)^3 - 3\left(\frac{r}{b}\right) + 2\right] \quad \text{for } a \leq r \leq b$$
$$= 0 \quad \text{for } r > b. \tag{4}$$

For comparison, when there is no uptake $\nu = 0$ and Expression 4 becomes

$$C = \frac{\lambda^2}{\alpha D} \frac{q}{3} \frac{a^3}{r}. \tag{5}$$

The consequences of diffusion and uptake are shown in Figure 26-3. Setting the radius of the cell

$a = 5$ μm, and assuming that the diffusing molecule is similar to serotonin (dopamine and a number of other neuroactive compounds have similar diffusion coefficients, see Gerhardt and Adams, 1982). Curves were calculated using Equations (3), (4), and (5) and plotted in Figure 26-3, where the legend further defines the parameter values used in the calculations. With semilogarithmic axes, the curve representing diffusion without uptake falls quite slowly; even at 500 μm the concentration is still 0.02 μM (not illustrated). In contrast, in the case of uptake, the concentration has fallen to zero by 50 μm away from the cell ($r = b$). This simple example illustrates a basic principle. If diffusion is the only process governing molecular migration, then eventually released molecules will spread large distances from the site of release. On the other hand, if uptake (or some form of degradation) is operative, then molecules will not get beyond a certain distance from the source.

LOCAL MODELS OF THE EXTRACELLULAR MICROENVIRONMENT

The interactions between neurons and glia often involve only issues about the influence of a single cell on its neighbor; in this case only very short-range diffusion effects are relevant and the local geometry becomes the dominant issue. The distance scale here would be less than 1 μm.

The classic model of this type is the interaction between the giant axon of the squid and its sheath of Schwann cells, first discussed by Frankenhaeuser and Hodgkin (1956) (Figure 26-1B). The model arose because these investigators noticed that a train of action potentials in the axon were accompanied by undershoots that declined in time. The decline was attributed to accumulation of K^+ adjacent to the axon and this led naturally to models of the environment surrounding the axon. Recent experiments have suggested that in axons in very good condition, the decline in the undershoot is smaller than that seen by Frankenhaeuser and Hodgkin, suggesting that the K^+ is effectively removed by Schwann cells in a variety of ways (Abbott et al., 1991; Brown and Abbott, 1993). Nevertheless the basic model of Frankenhaeuser and Hodgkin is relevant to any discussion of local interactions.

The Frankenhaeuser and Hodgkin Models

The first model consisted of a finite free space of thickness θ (cm) around the axon bounded by a very thin barrier to diffusion with a permeability P ($cm \cdot s^{-1}$). Defining the outflow of K^+ through the excitable membrane of the axon as M ($mmol \cdot cm^{-2} \cdot s^{-1}$), and assuming that there is no gradient in the space, this leads to the simple equation for the concentration C (mM) in the space

$$\theta \frac{dC}{dt} = M - PC. \quad (6)$$

Based on the available electrophysiological and anatomical data, Frankenhaeuser and Hodgkin identified the barrier with the surrounding Schwann cells, which were made permeable by the presence of narrow clefts between the overlapping glia. The space between axon and Schwann cell, θ, was estimated to be 30 nm, and the permeability, P, was estimated to be 6×10^{-5} $cm \cdot s^{-1}$. Recently these estimates were significantly revised by Astion et al. (1988). These authors, working on the small squid *Alloteuthis,* estimated that in extreme cases θ could be as large as 190 nm and P as large as 7×10^{-4} $cm \cdot s^{-1}$.

The second model consisted of a finite diffusion barrier extending directly from the membrane with no intervening space. The barrier was characterized in this model by an apparent diffusion coefficient D^*

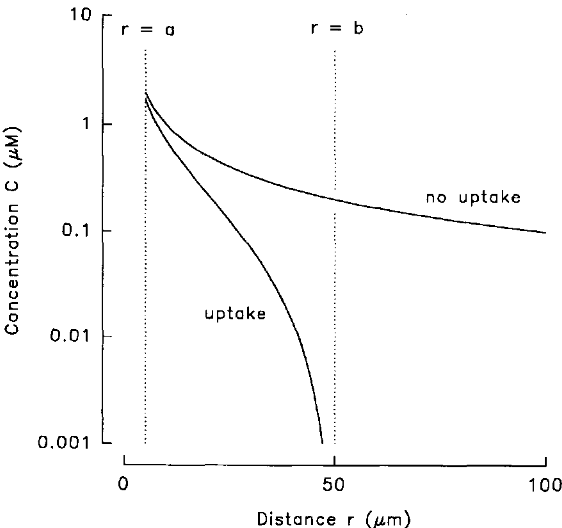

FIG. 26-3. Comparison of effects of simple diffusion and diffusion with uptake on the concentration profile of a small molecule migrating away from a cell in brain tissue in steady-state conditions. Abscissa is distance on a logarithmic scale and ordinate is concentration, on a linear scale. The radius of the cell is 5 μm ($r = a$), the free diffusion coefficient (D) is 5.4×10^{-6} $cm^2 \cdot s^{-1}$ (serotonin at 25°C), $\alpha = 0.2$ and $\lambda = 1.6$. The rate of generation of the substance was taken as 10 $\mu M \cdot s^{-1}$ and the rate of uptake as 0.01 $\mu M \cdot s^{-1}$. While the concentration of the substance falls slowly with distance when there is no uptake, the concentration falls rapidly when uptake is present and no substance migrates further than 50 μm ($r = b$) from the center of the cell. See text for further details.

(Frankenhaeuser and Hodgkin actually called this parameter D but D^* is used here to avoid confusion with the use of D to denote the free solution diffusion coefficient) for the barrier, which had a thickness l. It was assumed that concentration was zero at the outer edge of the barrier. Based on their electrophysiological data, Frankenhaeuser and Hodgkin arrived at values of $D^* = 2 \times 10^{-10}$ $cm^2 \cdot s^{-1}$ and $l = 540$ Å. Since the free diffusion coefficient for K^+ at the temperature of these experiments (18°C) is about 1.5×10^{-5} $cm^2 \cdot s^{-1}$ (Hodgkin and Keynes, 1953), Frankenhaeuser and Hodgkin were actually assuming a tortuosity of 274 for their diffusion layer. One noteworthy aspect of this model is that the barrier did not incorporate a volume fraction, so there was no discussion of how much K^+ was retained in this region.

Frankenhaeuser and Hodgkin found that the first model fitted their data better than the second, which did not predict the electrophysiological data well at early times. Moreover, the first model could be identified with anatomical structure. A more elaborate theoretical evaluation of these diffusion models has been provided by Taylor et al. (1980) (Figure 26-1C) who modeled the space described in Frankenhaeuser and Hodgkin's first model, the clefts between the Schwann cells and subsequent basement membrane, connective tissue, and unstirred layers. Most recently, there has been further interest in assessing the physiological role of the complex Schwann cell morphology and, as it is now appreciated, K^+ transport properties (Abbott et al., 1988, 1991; Astion et al., 1988; Brown et al., 1991; Brown and Abbott, 1993; Lieberman et al., 1993).

The type of models proposed by Frankenhaeuser and Hodgkin have been the basis for other considerations of K^+ homeostasis around cells in the central nervous system. Many fundamental ideas about the diffusion of substances in intercellular clefts and the interactions between neurons and glia were developed by Kuffler and Nicholls (1966), based on studies in the leech. Other examples include Lebovitz (1970), and Adelman and Palti (1972); but all these models were mainly directed to discussions of how accumulation of K^+ affected the electrical properties of cells. With the advent of ion-selective microelectrodes for K^+, other issues came to the fore such as accounting for spatial buffering of K^+. Nevertheless, the sort of models proposed by Frankenhaeuser and Hodgkin and by Taylor and colleagues could be applied to a variety of problems of neuron-glia interaction and, ironically, are probably not well suited to model K^+ because of its ready movement across membranes, but better suited to less permeable compounds.

SPATIAL BUFFERING OF POTASSIUM

The question of whether K^+ constitutes a signal in the BEM is still not totally resolved, but if it does, then glia undoubtedly play a role in controlling this communication channel. Many studies with ion-selective microelectrodes have shown that virtually all neuronal activity is accompanied by an increase in $[K^+]_0$. The normal baseline $[K^+]_0$ is generally taken as 3 mM, but two recent reports (Moghaddam and Adams, 1987; Coles and Poulain, 1991) have suggested that this could be an overestimate and that regional variations exist with values as low as 1.9 mM. If these measurements are correct, then $[K^+]_0$ does not simply reflect the concentration in the cerebrospinal fluid but is locally regulated, and this could involve glial cells. Leaving this interesting issue aside, it is well established that during synchronous activation of neurons, by electrical stimulation, for example, $[K^+]_0$ can rise by several mM and may even go as high as 12 mM, at which level a "ceiling" occurs that is only exceeded in the developing brain and in pathophysiologies such as anoxia and spreading depression. Reviews of studies of evoked changes in $[K^+]_0$ can be found in Walz and Hertz (1983) and Syková (1992).

Both neurons and glia respond to local increases in K^+ by depolarizing because the basic determinant of the membrane potential of all brain cells is the ratio of K^+ across the membrane. Thus the possibility of a widespread and effective signaling mechanism exits. If there is a fundamental flaw in this scenario it is the lack of specific receptors for K^+. All cells respond, so either there is a nonspecific depolarization of a population of cells, which may be functionally relevant, or the BEM has properties that channel K^+ to some cells and not others. These issues raise the question of how $[K^+]_0$ is controlled.

As first pointed out by Orkand et al. (1966), the fact that glial cells have membranes that apparently exhibit a very high selectivity for K^+ means that a special type of mechanism can be brought into play to disperse local accumulation of K^+. This *spatial buffering mechanism* has been analyzed in theory by Gardner-Medwin (1983b, 1986) and by Odette and Newman (1988) and Dietzel et al. (1989). The most extensive experimental evidence for spatial buffering has been obtained in the the retina (Gardner-Medwin et al., 1981; Coles and Orkand, 1983; Newman, 1986; Reichenbach, 1991; Oakley et al., 1992). The mechanism will be elaborated below, but suffice it to say that it depends solely on basic biophysical properties of membranes. An alternative mechanism for control of K^+ is that of energy-dependent transport, the best known example of which is the ubiquitous

oubain-sensitive Na^+-K^+ transporter that moves Na^+ out of cells and K^+ in (Ballanyi et al., 1987; see Chapter 16, this volume). Other transport mechanisms, such as ones that control pH (Chesler, 1990; Jendelová and Syková, 1991), can also move K^+, and passive accumulation of KCl is also possible (Gardner-Medwin, 1980; Ballanyi et al., 1987; see Chapter 18, this volume).

The relative merits of spatial buffering versus active transport have been debated extensively over the years. Useful accounts can be found in Cserr (1986), Barres et al. (1990), and Barres (1991). Barres and coworkers have tended to emphasize the importance of uptake compared to spatial buffering. These issues are addressed in several other chapters in this book (see Chapters 18, 31, 47). With the present emphasis on molecular mechanisms, transporters are likely to receive increasing attention in the years to come, and therefore this chapter discusses spatial buffering in some detail, since, like diffusion, it is a consequence of basic physical principles and therefore is always present, even if the brain has evolved more effective mechanisms to bypass it.

Mechanism of Spatial Buffering

The fundamental concept of spatial buffering is simple (Figure 26-4). If an elongated cell satisfies two conditions—i.e., (1) It is predominantly permeable to K^+ over other ions, and (2) It is bathed in a gradient of K^+ concentration—then the part of the cell

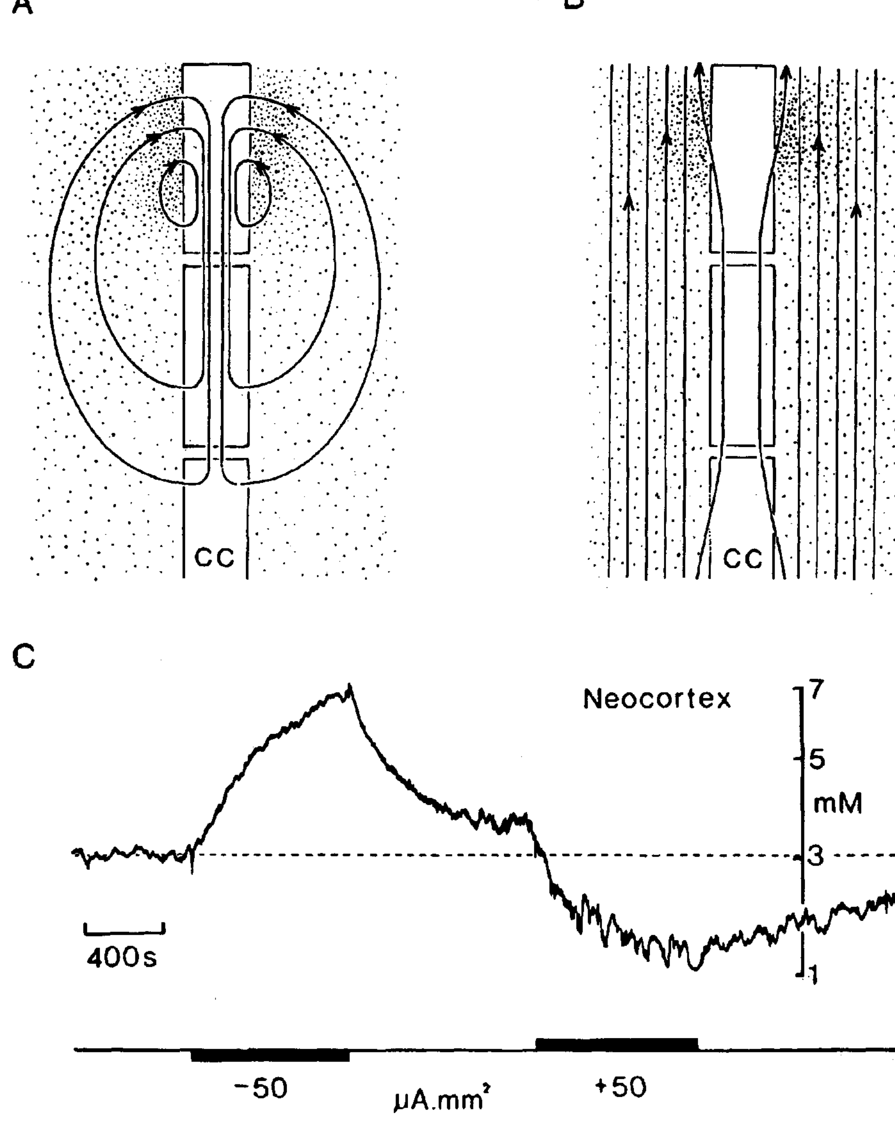

FIG. 26-4. Current-mediated spatial buffering of K^+. (A) A set of vertically oriented, electrotonically coupled core conductors (*cc*) or "transfer cells" that are subjected to a localized increase in $[K^+]_o$ (*density of dots*) over the upper cell surface. The gradient of $[K^+]_o$ causes the upper regions of the core conductor to be more depolarized than the lower, so that a current enters the cell in the upper region and exits over the lower surface in a distribution determined by the cable properties of the cells. Since the membranes of the cells are predominantly permeable to K^+, the current is carried by K^+, and consequently the circulating current rapidly dissipates the $[K^+]_o$ gradient. (B) The converse situation to that shown in Figure A. A vertically flowing current is imposed on a tissue containing vertical core conductors. Much of the current flows through the extracellular space, but some enters the cells in the lower regions and exits in the upper (the proportion and distribution are governed by the cable properties and various conductivities involved). Again, assuming that the membranes are predominantly permeable to K^+, the current carries this ion into the cell in depth and out of the cell superficially, thereby depleting and augmenting $[K^+]_o$, respectively. (C) An experiment in the rat neocortex to verify the concepts diagrammed in Figure B. A current density of 50 $\mu A \cdot mm^{-2}$ is applied, with the brain surface negative and $[K^+]_o$ recorded just beneath the surface. $[K^+]_o$ slowly rises by several mM. When the current is reversed so that the surface is made positive, $[K^+]_o$ falls. [From Nicholson (1983), with permission.]

that is bathed in the higher K^+ concentration will be more depolarized than the other part that is in the lower concentration. Current will flow into the region that is more depolarized and out of the other region, but, since the membrane is dominated by potassium permeability, the current will be carried by this ion, rather than Na^+ or Cl^-. Consequently, K^+ will enter the cell where it is depolarized, which happens to be where the extracellular K^+ is highest, and K^+ will leave where the extracellular K^+ is lowest, thus the gradient of K^+ surrounding the cell will be dissipated. If the permeability of the membrane to K^+ is sufficiently high, then the dissipation process can be very rapid, since it is mediated by electric current flow, and exchange with intracellular ions rather than to actual movement of ions over large distances. Glial cells do indeed appear to have the requisite K^+ permeability, but recent findings suggest that the channels are all voltage-sensitive inward rectifiers (Barres et al., 1990), which may imply that K^+ enters cells more easily than it leaves. A second problem, recognized early in the theory, is that the short length constant of glial cells and short physical length might preclude movement of K^+ over significant distances; however, the evidence for extensive coupling of glial cells is often mentioned as a solution to that problem (see Chapter 19, this volume).

The real issues cannot be dealt with completely by simple intuitive models, however, and it is fortunate that Gardner-Medwin has developed an extensive theoretical framework for the discussion of spatial buffering, which has been little used to date. Given our greatly expanded knowledge of glial cell properties, it would now be worthwhile to reconsider the issues in the light of this model.

Gardner-Medwin has provided three definitive papers (Gardner-Medwin, 1983a, 1983b; Gardner-Medwin and Nicholson, 1983) and a final and important paper (Gardner-Medwin, 1986) extending some of the ideas. Other papers, dealing with implications for pathophysiology are referenced in the four cited papers.

No attempt here will be made to describe in detail the theoretical model of Gardner-Medwin; rather the goal will be to indicate the importance of the results. The papers are based on a combined experimental and theoretical approach. The experiments are based on a clever innovation. If the spatial buffer hypothesis is correct, then it must be possible to "run it backwards." In other words, if the distribution of K^+ in the brain is initially uniform and we apply a steady current so that a *potential* gradient is established, then K^+ will enter glia cells where they are subject to highest potential and leave where the potential is lowest, and this will lead to $[K^+]_0$ depletion in the one region and accumulation in the other. A gradient in extracellular K^+ will therefore be *created*, and this can be measured in a variety of ways (Figure 26-4). This prediction was completely verified in several experiments, and, moreover, shown to be an extremely robust phenomenon that persisted when transport systems were blocked (Gardner-Medwin and Nicholson, 1983), supporting the idea that it is a fundamental biophysical property.

The second part of Gardner-Medwin's work developed a detailed model of the processes involved in both the normal spatial buffer mechanism and when it was reversed. While the ideas are simple at one level, they are complex at another, since it is necessary to combine (1) the coupling of potential gradients with chemical gradients and diffusion and (2) the electrotonic behavior of the leaky distributed structures that represent glia and neurons. Item 1 involves solving the Nernst-Planck equation and item 2 involves the application of cable theory. The combination leads to formidable equations that require numerical solution. It is worth noting that in all his formalism Gardner-Medwin referred to the mediators of spatial buffering as "transfer cells" to avoid categorically identifying them with glia.

Even without a detailed analysis, it is fairly evident that the extent to which a population of glia implement spatial buffering will depend on factors of geometrical distribution. In particular, the relation between the spatial extent of the potassium inhomogeneity and the length constants of the cells involved. This issue of what types of potassium distribution could be effectively dissipated by spatial buffering and which would be more amenable to uptake was the topic of Gardner-Medwin's work (1986), where the concept of spatial frequencies was introduced to characterize distributions.

CONCLUSIONS

There is little doubt that the extracellular space is an effective conduit for the movement of molecules and there is little doubt that both neurons and glia release substances into this space, consequently there must be a continual molecular traffic between cells and cell populations. This flow can be channeled by local architecture of the extracellular space and by mechanisms that remove the chemical messengers from the extracellular space. While we have no clear picture of this control system at present, glial cells, which often exhibit massive membranous expansions, seem very well suited to play a major part in the regulation of molecular traffic in the extracellular microenvironment.

I thank Dr. Margaret Rice and Dr. Jonathan Coles for suggestions for improving this manuscript. This work was supported by NIH Grant 28642.

27 Functional significance of glial-derived matrix during development and regeneration

ROBERT J. MCKEON AND JERRY SILVER

In the last decade, our understanding of the role glial cells play in the developmental and regenerative potential of the nervous system has increased dramatically. However, while it is clear that neuroglial cells are involved in neuronal migration (Hatten, 1990; Rakic, 1990), process outgrowth during development (Silver, 1984; Bovolenta and Mason, 1987; Silver et al., 1993), and regenerative failure within the adult central nervous system (CNS) (Reier and Houle, 1988), the molecular mechanisms involved in these events are only recently becoming clear. In this chapter, we review the various roles played by glia, specifically astrocytes, during development with special emphasis on, first, the cell-surface molecules associated with these cells and, second, glycoproteins and proteoglycans secreted by these cells into the extracellular matrix (ECM), which have been suggested to influence axonal outgrowth. Particular emphasis is placed on the molecular changes that occur within these cells once development is complete and the effect these changes have on axonal regeneration. Because this review focuses on the role played by only one type of neuroglial cell, the astrocyte, during vertebrate development and regeneration, the reader is referred to Chapters 57 and 59 in this volume for reviews of the two other major neuroglial cell types, oligodendrocytes and microglia.

HISTORICAL COMMENTS

Glial Structures as Axonal Pathways

The intimate relationship between growing axons and glial cells was perhaps best highlighted in 1928 when Ramón y Cajal documented an association between regenerating axons and glia (Schwann cells) within the sciatic nerve of the peripheral nervous system (Ramón y Cajal, 1928). However, it was not until much later that a similar role played by CNS glia was as clearly demonstrated. Singer et al. (1979) reported that during the development or regeneration of spinal cord axon tracts in the lizard, extracellular spaces between glial cells were present, which seemed to form longitudinal "channels" ahead of the leading axons. It was suggested that these channels may provide a physical and/or chemical pathway for axon growth. Interestingly, elongating axons were always found associated with the glial processes that formed the walls of the channel. Similarly, Silver and Robb (1979) reported the presence of preformed glial channels within the retina of embryonic day 10 mice, 2 days prior to the growth of optic axons out of the eye. Evidence that these channels were involved in axonal growth was provided by studies using the ocular retardation mouse mutant (*orj*) in which the channels between the primitive glial processes are reduced in size to approximately 10% of those found in the normal mouse retina. In this mutant, retinal ganglion cell axons never leave the eye. Instead, large neuromatous whorls of growing axons form at the interface between the retina and the pigmented epithelium. These data suggested that a change in the glial environment in *orj* mutants may have been involved with the failure of optic fibers to grow out of the eye (Silver and Robb, 1979). However, while it had now been suggested that the environment created by glia was important for the development of certain long-fiber projections, it was not clear whether the association between growing axons and glia was simply due to the available space provided by glial channels or whether there was a more active, molecular association between these two cell types.

In 1984 another primitive glial structure that influenced the direction of optic fibers was reported at the boundary between the diencephalon and telencephalon (Silver, 1984). In this region, central projections from optic and olfactory regions converge but remain segregated and project to different areas of the brain. Precisely at the area where these two projections converge, a "knotlike" structure of spe-

cialized neuroepithelium, which eventually differentiate into glia, was discovered. Just prior to the arrival of axons, this area undergoes a significant amount of cell death and subsequent remodeling to form a compacted cellular architecture. When growing fibers reach the "knot" it consists of a dense cluster of interwoven nonneuronal cells that lack marginal radial processes and whose cell bodies directly abut the glial limiting membrane. The morphology of this area is in sharp contrast to the channelized marginal zone and lengthy glial endfoot regions along which axons tend to grow normally. It was suggested that, due to the absence of large extracellular spaces and the elimination of the marginal zone processes, the specialized glia within the diencephalic-telencephalic junction may serve as an axon refractory area, or boundary, which served to separate the optic and olfactory projections.

Another example of the interaction between growing axons and glial structures occurs during the development of the corpus callosum. As the fibers within the callosum project toward the midline, they are faced with a number of decisions. At the corticoseptal interface, callosal fibers continue across the midline in order to terminate in the opposite hemisphere, thereby passing up another potential target, the septum. Present in this area is a unique glial structure, which may help influence this choice. This structure has been described as a glial "sling," which develops at the midline during the growth of the first callosal axons (Silver et al., 1982). This "sling" consists partly of radial astroglia and partly of a dense mat of primitive subventricular cells that is located dorsal to the partially fused septum. Because the initial callosal axons migrate along the dorsal surface of this structure in order to cross the midline, it has been proposed that the glial "sling" specifically functions to guide callosal axons across the midline at the point where the two cerebral hemispheres begin to fuse (Silver et al., 1982).

While it has been suggested that the glial "sling" is involved in guiding the initial callosal axons, the region of the "sling" is only 200 to 250 μm long. However, by the time its development is complete, the corpus callosum will have expanded rostrally and be approximately 2 mm wide. Thus, while the glial sling may be involved in the initial stages of callosal development, other mechanisms must contribute to the formation of the rest of this projection. Specifically, axon fasciculation and specialized glia that are associated with the continued fusion of the telencephalic midline in a rostral direction (Hankin and Silver, 1986) leads development of the callosal commissure (Silver et al., 1993).

In summary, these studies served to reinforce the concept of an *in vivo* axonal/glial interaction that helps to determine the extent and direction of axon outgrowth. However, axons can be directed in two ways. First, astroglia may provide preferred pathways for axon outgrowth or, second, they may serve as barriers in precise locations to prevent the growth of certain axon pathways into inappropriate areas.

ROLE OF CELL AND SUBSTRATE ADHESION MOLECULES IN AXON-GLIA INTERACTIONS

Cell Adhesion Molecules

Up to this point, we have discussed glial structures that may direct or segregate growing axon pathways. This is not to imply, however, that axons interact with glia due strictly to the location or density of specialized subpopulations of these nonneuronal cells. Rather, it is now known that, *in vitro,* axons actually prefer to grow on (Noble et al., 1984; Fallon, 1985), or specifically avoid (Grierson et al., 1990), particular types of glial cells. Attractive versus repulsive glial surfaces have been most clearly demonstrated when axons are given a choice between different cell types (Noble et al., 1984, Fallon, 1985). In cases where glial cells form an attractive surface, it was suggested that this association was due to the expression of specific cell and substrate adhesive molecules, including the neural cell adhesion molecule (NCAM) (Noble et al., 1985), N-cadherin (Neugebauer et al., 1988; Tomaselli et al., 1988), and laminin (Liesi et al., 1984).

NCAM. *In vivo,* NCAM has been shown to be associated at the endfoot region of primitive glia and on the marginal radial process of neuroepithelial cells in areas of the optic pathway (Silver and Rutishauser, 1984). It is in this NCAM-positive area that most early growth cones are found and is thus consistent with the marginal location of the pioneering optic fibers (Silver, 1984). Additionally, when anti-NCAM Fab's are injected into the early developing eye cup of chicks, the optic fibers dislocate from the glial limitans as they exit the eye (Silver and Rutishauser, 1984). These data are consistent with the proposed interaction between axon outgrowth and NCAM-producing neuroepithelial cells within the retina. Finally, neuroepithelial cells within the glial "knot" (described above) do not express NCAM during the time of initial axon outgrowth nor later in development (Silver et al., 1987). Along with the morphological changes in this region, the absence of NCAM may contribute to the glial "knot's" function as an axon-refractory area (Silver et al., 1987).

N-Cadherin. Another molecule involved in promoting neurite outgrowth on glia is N-cadherin (Neugebauer et al., 1988; Tomaselli et al., 1988), which is one member of a family of Ca^{+2}-dependent cell adhesion molecules. N-cadherin appears to be the predominant cadherin in the CNS and has been implicated in neurite outgrowth, since it serves as a potent substrate for the growth of ciliary ganglion neurons in a manner that differs from laminin (Bixby and Zhang, 1990). N-cadherin is present on both neurons and glia (Hatta et al., 1987) where it appears to function via a homophilic binding mechanism. N-cadherin helps promote neurite outgrowth on substrates of astrocytes (Neugebauer et al., 1988) or Müller cells (Drazba and Lemmon, 1990). Finally, N-cadherin may be involved in axon fasciculation, since antibodies to N-cadherin caused a significant change in the morphology of retinal ganglion cell axons, without a change in the amount of outgrowth, when grown on a substrate of purified laminin (Drazba and Lemmon, 1990).

Glia-Derived Nexin. To this point, we have discussed the role of glial-associated molecules that promote neurite outgrowth by providing an adhesive substrate for growing neuronal processes. However, other mechanisms that can promote neurite outgrowth by regulating the degradation of the ECM by protease inhibitors have been described (Monard, 1990). One of the best characterized protease inhibitors is the glia-derived nexin (GDN). This 43 kD protein, present in medium conditioned by glioma cells or primary astrocytic cultures, serves as both a neurite-promoting factor for a variety of cell types and a specific inhibitor of serine proteases, such as thrombin and trypsin (Farmer et al., 1990). Recent evidence has demonstrated that the protease inhibitory activity of GDN is crucial for promoting neurite outgrowth from hippocampal neurons (Farmer et al., 1990). GDN is abundant on the surface of astrocytes and also binds to the ECM, possibly by a heparinlike molecule (Halfter et al., 1989). In adult animals, GDN is most highly expressed in the olfactory system, where it has been suggested to play a role in the continued growth of olfactory neurons through adulthood by interacting with cell adhesion molecules, that is, L1 and/or N-CAM, and possibly laminin to promote neurite outgrowth from these cells (Doucette, 1990). In fact, the interaction between protease inhibitors present in astroglial-conditioned media and laminin have been suggested to be necessary for prolonged neurite outgrowth (Shea et al., 1992). In this model, the rapid elaboration of unstable neurites has been shown to be due to the action of glial-derived protease inhibitors. This rapid neuritogenesis is then thought to be stabilized by ECM components, specifically laminin, allowing for the continued elongation of growing neurites (Shea et al., 1992).

Substrate Adhesive Molecules

Laminin. In addition to the role of cell surface adhesion molecules, substrate adhesive molecules produced by glia and secreted into the extracellular matrix have also been implicated in axonal guidance (Cohen et al., 1986; Liesi and Silver, 1988). Punctate deposits of laminin have been localized near the endfeet of neuroepithelial cells in the developing mouse (Liesi and Silver, 1988) and chick optic system prior to the arrival of the first optic axons (Halfter et al., 1983). The location of these deposits within developing axon tracts is consistent with the *in vitro* observation that glial cells are capable of producing laminin and promoting robust axon outgrowth. However, similar to the expression of NCAM, laminin is only present within developing axon tracts, in close approximation to growing axons, at early stages. As the optic system matures, laminin expression decreases (Cohen et al., 1986; Liesi and Silver, 1988), and molecules involved in axon fasciculation, such as L1 (Lagenaur and Lemmon, 1987), may take on a more important role (Schlosshauer and Dutting, 1991). Consistent with its presence on glia within the optic system, laminin is also associated with glia during the development of the corpus callosum, fornix, and pathways in the embryonic hindbrain (Liesi and Silver, 1988). Finally, Smith et al. (1986) demonstrated that immature activated glia are capable of depositing laminin onto a Millipore filter in a model of axon guidance of the corpus callosum. Since laminin is an extremely potent factor for neurite outgrowth *in vitro* (Liesi et al., 1984), its location on astrocytes during development suggests that it may also serve as a growth-promoting factor *in vivo*.

Molecular Aspects of Immature Glia

Effect of Antibody Perturbations on Axon Growth on Astrocytic Substrates. Because of *in vitro* and *in vivo* studies on the localization of both cell and substrate adhesive molecules during development, subsequent experiments sought to clarify the function of molecules on the surface of astrocytes thought to be involved in promoting neurite outgrowth. Previous studies had demonstrated the presence of laminin (Liesi et al., 1983) and the cell adhesion molecules NCAM and N-cadherin (Neugebauer et al., 1988) on astrocytes. In order to determine whether these adhesion molecules were involved in axon out-

growth, recent studies (Tomaselli et al., 1988; Smith et al., 1990) utilizing function-blocking antibodies to several of these molecules (i.e., N-cadherin, NCAM, and L1), or their receptors (i.e., β1-class integrin), have demonstrated that neurite outgrowth on an astrocytic substrate is decreased in the presence of these reagents. However, in order to achieve the maximal inhibition, a number of different antibodies were required simultaneously. These studies suggested, first, that these molecules are directly involved in promoting neurite outgrowth on astrocytes *in vitro,* but, second, that neurites use more than one type of molecule or mechanism to extend across an astrocytic surface. Unfortunately, whether these same molecules and their receptors are equally capable of promoting axon outgrowth *in vivo* is still not known.

INHIBITORY MATRIX MOLECULES ASSOCIATED WITH ASTROGLIA IN BOUNDARY AREAS DURING DEVELOPMENT

While astroglia may promote neurite outgrowth through the expression of various cell and substrate adhesive molecules, certain subpopulations of astrocytes may serve as barriers to the advance of axons and thereby influence the direction of process outgrowth via a repulsive mechanism. In this regard, during development astrocytes have been shown to secrete certain molecules into the surrounding ECM that can actively repel axon growth cones. One class of putative inhibitory matrix molecules associated with astrocytes are the proteoglycans (PGs). Proteoglycans consist of a protein core to which are attached various glycosaminoglycan side chains (GAG) (Margolis and Margolis, 1989). Proteoglycans are usually classified by the composition of these GAG side chains and consist of chondroitin sulfate, dermatan sulfate, heparan sulfate, and keratan sulfate (Margolis and Margolis, 1989). Due to their size and the heterogeneous nature of these side chains on a particular core protein, the specific composition of proteoglycans can be quite diverse (Herndon and Lander, 1990). However, it is clear that a number of different forms are present in the nervous system (Herndon and Lander, 1990), are synthesized by both neurons and glia (Gallo and Bertolotto, 1990; Flaccus et al., 1991; Johnson-Green et al., 1991), and the different forms can have different functions (Chiu et al., 1986; Snow et al., 1990a, 1990b). As an example of this diversity, it is known that heparan sulfate PG can interact with laminin to form a complex that promotes neurite outgrowth (Dow et al., 1991). Alternatively, certain keratan sulfate PGs (Cole and McCabe, 1991; Geisert and Bidanset, 1993) and chondroitin sulfate PGs (CS-PG) (Snow et al., 1990b) have been shown to inhibit neurite outgrowth when used as a substrate in culture. Initial work in our laboratory with a cartilaginous CS-PG has demonstrated that the GAG side chains were responsible for inhibiting neurite outgrowth *in vitro* (Snow et al., 1990b), although the protein core has also been implicated (Oohira et al., 1991).

Since CS-PG is capable of restricting neurite outgrowth *in vitro,* might this molecule be involved in forming barriers to growing axons during development? Recently, our laboratory, as well as others (Steindler et al., 1989; Cole and McCabe, 1991; Geisert et al., 1992), have examined the expression of these inhibitory molecules in a number of areas normally refractory to axon outgrowth during development.

The Roof Plate

As described above, structures composed of specialized nonneuronal cells are often located in regions of the CNS where they may serve as barriers to growing axons. These barriers may restrict axon outgrowth simply due to their physical properties, as has been suggested to occur during scar formation (Reier and Houle, 1988), or they may actively direct growing axons to other regions by expressing specific growth inhibitory molecules on their cell surface or in the surrounding ECM (Steindler et al., 1989). One area that has been closely examined is the roof plate of the developing spinal cord (Snow et al., 1990a). Located along the dorsal midline, the roof plate consists of glial cells that undergo a morphologic change between embryonic days 12.5 and 15.5. At this earlier time point, the roof plate glia are organized into a wedge-shaped structure, with large extracellular spaces between the cell apices. By embryonic day 15.5, the cells in this area have become reorganized into a dense midline septum, stretching from the pia mater to the central canal. Concomitant with this morphologic change, the roof plate glia begin to express a keratan sulfate-chondroitin sulfate proteoglycan (KS/CS-PG), a molecule unique to these cells. The expression of this molecule is coincident with the growth of axons along, but never across, the dorsal midline. The expression of this molecule is consistent with the observation that KS/CS-PG can inhibit neurite outgrowth *in vitro* (Snow et al., 1990b; Geisert and Bidanset, 1993). These data suggest that the expression of this, and potentially other, inhibitory molecules to axon outgrowth may form not only a physical barrier but also a molecular barrier to growing axons.

The barrier function of the roof plate glia has been further examined in the developing optic projection to the hamster tectum (Snow et al., 1990a; Wu et al., 1990). By creating a carefully placed lesion in the roof plate prior to axonal elongation in this area, Wu et al. (1990) were able to show that aberrant optic projections would cross through the lesioned area and expand into the denervated tectum, a situation that does not occur in normal nor sham-lesioned control animals. Similar to the expression seen in the rat, KS/CS-PG was also localized to the roof plate in the hamster tectum (Snow et al., 1990a; Wu et al., 1991) where it may be involved in preventing elongating axons from expanding across the midline and into inappropriate target areas.

Olfactory Bulb

Recently, it has been suggested that astroglia may be involved in the development of olfactory glomeruli, unique morphologic structures within the olfactory lobe (Gonzalez and Silver, 1993). The olfactory glomeruli are unique because in this area axons form exceptionally tight bundles among the primary dendrites of mitral cells located in the olfactory bulb (Graziadei and Monti-Graziadei, 1980). Although olfactory axons are capable of regenerating throughout life, they never penetrate deeply into the bulb, consistently terminating within the glomeruli (Graziadei and Monti-Graziadei, 1980). In the olfactory bulb of the moth, *Manduca sexta,* Tolbert and Oland (1990) have suggested that glia are involved in glomerular formation, since glial elements define the periphery of the glomeruli for primary olfactory axons and the dendrites of the second-order neurons. Similarly, in the rat olfactory bulb, Bailey and Shipley (1992) have described a number of astrocytic subtypes in the different layers of the bulb and a highly specific relationship with the glomerulus. Finally, Valverde et al. (1992) have suggested that it is the interactions between olfactory axons and bulb glia that initiated the formation of the glomeruli.

In order to examine the molecules involved during the formation of the glomeruli, Gonzalez et al., (1993) recently compared the expression of a specific label for growing olfactory axons, olfactory marker protein, with markers for both immature and mature astroglia, the astroglia-associated ECM glycoconjugate, CS-PG, and cytotactin/tenascin (CT). Cytotactin/tenascin was examined because of its close association with CS-PG (Crossin et al., 1989) and because previous studies have demonstrated that this molecule is involved in the formation of glial barriers within the cerebral cortex (Crossin et al., 1989; Steindler et al., 1989).

The results of these experiments demonstrated that both CS-PG and CT are associated with astrocytes prior to formation of the glomeruli. During later developmental stages, the expression of these molecules changes as astroglia migrate into regions surrounding the developing glomerulus. Now, rather than being somewhat uniformly expressed within the olfactory bulb, CS-PG and CT are expressed on astrocytes which form a ring around the glomerular border. Olfactory axons fail to grow beyond the glomerulus once the increased expression of these molecules has occurred. These data suggest that these molecules are involved in the formation of a barrier to ingrowing axons both during development and throughout the life of the animal.

Retina

To this point, we have described studies that suggest that certain extracellular matrix molecules associated with glia are involved in axonal pattern formation within the CNS. Additional evidence from our laboratory, using the developing rat retina as a model, has demonstrated that these same molecules may also have a role in controlling retinal ganglion cell differentiation (Brittis et al., 1992) as well as the direction of the growth of their processes (Snow et al., 1991). On embryonic day 12, CS-PG is present throughout the retina. By embryonic day 13, CS-PG disappears from the center of the retina, just dorsal to the optic fissure. The CS-PG negative area is the first to become immunoreactive for the neuronal marker, TUJ1, which labels an isoform of β-tubulin found only in cells generating an axon. By embryonic day 14, the area of the retina positive for CS-PG has receded to the periphery, while the area in the center, positive for TUJ1, has expanded into areas previously CS-PG positive. By embryonic day 16, CS-PG staining is restricted to the dorsal and ventral poles of the retina, while TUJ1-positive axons of the retinal ganglion cells are present throughout the retina. Interestingly, retinal ganglion cells at the interface between the receding wave of CS-PG and the expanding zone of TUJ1-positive axons remain in an axonless, primitive state. Only as CS-PG expression continues to recede do these cells begin to put out axonal processes. Therefore, it has been hypothesized that neurons differentiate and extend axons toward the optic fissure in the center of the retina, at least in part, because the expression of CS-PG remains highest at the periphery. This possibility received support from additional experiments using chondroitinase ABC to remove the CS GAG side chains from the protein core (Brittis et al., 1992).

Retinas allowed to develop *in situ* in the presence of this enzyme demonstrated both ectopically placed retinal ganglion cell bodies and a severely perturbed distribution of ganglion cell axons, including some directed away from the optic fissure. Taken together, these data suggest that a receding wave of CS-PG within the retina may help control the timing of retinal ganglion cell differentiation and the direction of axon outgrowth by limiting the direction developing axons can grow.

Barrel Fields

Another glial-associated matrix molecule that may play a role in the formation of barriers is cytotactin-tenascin (Crossin et al., 1989; Steindler et al., 1989). CT is produced by astrocytes (Grumet et al., 1985) and secreted into the ECM where it is often found associated with CS-PG (Crossin et al., 1989). As mentioned earlier, CT is expressed in proposed barrier regions, such as the glomeruli of the olfactory bulb (Gonzalez et al., 1993) and also in regions of glial scarring following cortical (McKeon et al., 1991) and cerebellar injury (Laywell et al., 1992). Additionally, it has been demonstrated that both PNA-lectin binding glycoconjugates and CT are associated with astrocytes in boundary regions of somatosensory cortical whisker barrels (Steindler et al., 1989; Crossin et al., 1989). Steindler et al. (1989) have suggested that these molecules may be involved in the formation of functionally segregated domains within the somatosensory cortex, thereby preventing neurites from crossing into functionally distinct domains. This hypothesis has received support from experiments which examined barrel formation following whisker ablation and demonstrated a shift in the barrier formation of the barrel fields, consistent with the extent of whisker ablation (Crossin et al., 1989).

Additional evidence that CT can serve as an inhibitory molecule comes from *in vitro* studies which have demonstrated that CT can limit cell migration (Crossin et al., 1989) and, when used as a substrate in a choice assay, is inhibitory to neurite outgrowth (Faissner and Kruse, 1990). *In vitro,* subpopulations of astrocytes express CT on their surface (Grierson et al., 1990). When neurite outgrowth on cultured astrocytes was examined, it was observed that neurites grew only on CT-negative astrocytes while avoiding those astrocytes that expressed CT (Grierson et al., 1990). Treating confluent astrocytic cultures with fibroblast growth factor (FGF) increased the percentage of astrocytes that were CT-positive, with a concomitant decrease in the amount of neurite outgrowth on this substrate (Petroski et al., 1991).

Although there is evidence to suggest that CT can serve as an inhibitory molecule, there is additional evidence to suggest that it can also serve as an adhesion molecule (Locher et al., 1991). Recent evidence has suggested that CT contains both cell-adhesive and -inhibitory domains (Prieto et al., 1992; Chapter 28, this volume). The response of any particular cell type to CT may depend on its interaction with a specific domain of this multifunctional molecule. For additional details regarding the possible functions of this complex molecule the reader is referred to Chapter 28.

CHANGING ROLE OF ASTROCYTES DURING DEVELOPMENT AND REGENERATIVE FAILURE

From the studies cited above, it is now clear that astrocytes can promote neurite outgrowth both *in vivo* during development (Silver, 1984) and *in vitro* (Noble et al., 1984; Fallon, 1985), and that subpopulations of astrocytes in discrete regions are involved in forming barriers during development (Silver, 1984; Silver et al., 1993). It is equally well established that astrocytes are also involved with regenerative failure within the CNS of mature animals following injury (Reier and Houle, 1988). Consequently, a change in the neurite promoting capabilities of astrocytes must occur as nonamphibian animals mature (Geisert and Stewart, 1991).

In Vivo *Studies*

Evidence to support this hypothesis comes from studies utilizing the corpus callosum as a model for regeneration. Smith et al. (1986) lesioned the corpus callosum in neonatal mice, prior to the complete formation of this pathway. At the same time they implanted a piece of Millipore filter paper into the lesioned cavity and assessed whether the callosum would continue to develop. Microscopic analysis revealed that a layer of intensely GFAP-positive astrocytes had migrated onto and now covered the implant. Although apparently reactive, these immature astrocytes were capable of allowing neurite outgrowth, since a large number of axonal processes were seen in close association with these cells. In contrast, when implants were placed into the lesion cavity of older animals, no neurite outgrowth was seen across the implant. Again, intensely GFAP-positive astrocytes were present on the implant as seen in younger animals, but these seemed incapable of supporting neurite outgrowth. This observation

was further extended when cultures of purified astrocytes were grown on Millipore implants prior to implantation. Astrocytes derived from neonatal cortex and maintained in culture for less than 1 week were capable of supporting neurite outgrowth even when implanted into the lesioned callosum of adult animals. Astrocytes allowed to "age" in culture longer than 1 week were not able to support neurite outgrowth and again resulted in a lack of axon extension along the surface of the implant (Smith et al., 1986). These data suggested that a critical period existed for the neurite-promoting abilities of astrocytes. Prior to postnatal day 8, astrocytes were capable of promoting robust neurite outgrowth even in the callosum of adult animals where regenerative failure usually occurs. After this time point, it was hypothesized that changes occurred as the astrocyte matured that made it more refractory to axon outgrowth.

Explant Studies of the Glial Scar

The hypothesis that astrocytes become a less conducive substrate for neurite outgrowth after the critical period was further extended by studies that utilized an *in vitro* approach to analyze neurite inhibitory factors involved in glial scarring (Rudge and Silver, 1990). A piece of Millipore was placed into the gray matter of the cerebral cortex in neonatal or adult animals. After time points ranging from 6 to 10 days, the implants were removed, placed in culture, and used as a substrate for embryonic hippocampal neurons. When neurite length was assessed, significantly longer neurites grew on the surface of implants removed from neonatal as opposed to adult animals. This was not attributed to the presence of neuronotoxic substances or inaccessibility of the astrocyte surface. Rather, it was suggested that the inability of glial tissue removed from an adult animal to support neurite outgrowth was due to the expression of molecules on the surface of the astrocyte that inhibited axon outgrowth either directly or indirectly by occluding growth promoting factors found either on the surface of the astrocyte or within the surrounding extracellular matrix (Rudge and Silver, 1990).

Molecular Aspects of Mature Glia

While it was apparent that astrocytes removed from mature animals were not as capable of supporting neurite outgrowth as those obtained from neonatal animals, the molecules involved in this change had not been identified. As previously mentioned, antibodies to NCAM, N-cadherin, and the integrin β1 laminin receptor have been used to demonstrate the role these molecules play in neurite growth on substrates of immature astrocytes (Tomaselli et al., 1988; Smith et al., 1990). In order to determine whether a change in the expression of these molecules was involved in the decreased ability of mature astrocytes to support neurite outgrowth, astrocytes were first allowed to "age" in culture (Smith et al., 1990). Neurite outgrowth on these aged astrocytes was then assessed in the presence or absence of antibodies to these adhesion molecules or their receptors. Interestingly, the reduction in the amount of neurite outgrowth on "mature" astrocytes in the presence of these antibodies was significantly less than the reduction seen on immature astrocytes (Smith et al., 1990). These data suggested that a decreased expression of these molecules on mature versus immature astocytes may underlie the changes seen in the ability of astrocytes to support neurite outgrowth over time. However, while neurite outgrowth can be decreased by antibody perturbations of adhesive molecules or their receptors, the amount of neurite outgrowth that occurs on cultured astrocytes, both immature and "aged," is still significantly greater than that seen on glial scars removed *in toto* from the cerebral cortex of adult animals (Rudge and Silver, 1990). This suggests that there are other factors present *in vivo* which further modify the glial scar and make it an even more nonpermissive substrate for neurite outgrowth.

REEXPRESSION OF INHIBITORY MATRIX MOLECULES IN SUBPOPULATIONS OF REACTIVE GLIA AFTER INJURY

Since previous studies *in vivo* have demonstrated that glia-associated proteoglycans are present in areas of the developing CNS that are nonpermissive for axon outgrowth, we decided to examine whether these same putative inhibitory molecules were, first, present in an area of glial scarring and, secondly, whether those molecules associated with reactive glia were capable of inhibiting growing neurites.

Expression of Inhibitory Molecules Following Injury

In order to examine the expression of both adhesive and putative inhibitory matrix molecules after injury, we again utilized the filter implant paradigm described above (McKeon et al., 1991). When placed into the cerebral cortex of neonatal rats, Millipore filters elicited an increase in the number of GFAP-positive astrocytes. This increase was appar-

ent after 6 days and persisted for at least 30 days. These reactive astrocytes were present within the pores of the filter implant as well as on the surface and within the parenchyma of the brain surrounding the implant. Interestingly, unlike mature astrocytes in culture, increasing amounts of laminin and fibronectin were detected on the surface of the implant over time, consistent with the suggestion that, *in vivo,* a population of astrocytes was capable of maintaining the expression of these potentially growth-promoting extracellular matrix molecules. Finally, the distribution of collagen type IV was examined and determined to be limited to blood vessels growing across the surface of the implant.

When identical filters were implanted into young adult animals the distribution of reactive astrocytes, laminin, fibronectin, and collagen type IV was, surprisingly, similar to that seen in neonatal animals at the same postimplantation time points. Significantly different, however, was the expression of two putative inhibitory extracellular matrix molecules, CT and a CS-PG. Both molecules were found associated with reactive astrocytes either on the surface or within the pores of the filter implant. Interestingly, astrocytes within the surrounding areas of the brain were intensely GFAP-positive, but were CT and CS-PG negative. These data demonstrated that there was a differential expression of putative inhibitory molecules in older versus neonatal animals on a subpopulation of astrocytes intimately associated with the implant. This suggested that only a subpopulation of astrocytes may be functionally reactive, that is, associated with inhibitory molecules, despite the fact that there was a significant increase in the expression of GFAP in a greater number of astocytes surrounding the implant.

The proposed axon inhibitory function of these molecules after direct cortical injury is supported by an *in vivo* model of regenerative failure after indirect spinal cord injury. Prior to, but not after, postnatal day 3, damaged processes of sensory neurons in the dorsal root ganglion can regenerate into the spinal cord through the dorsal root entry zone (Carlstedt, 1988). Recently, this 3-day "critical period" was correlated to the distribution of CS-PG and CT (Pindzola et al., 1993). At late embryonic and early postnatal stages, both CT and CS-PG were colocalized to a small group of astroglia in the midline of the spinal cord, just lateral to the roof plate. Between postnatal days 1 and 3, the expression of these molecules spreads laterally through the dorsal root entry zone. Thus, the temporal distribution of these inhibitory molecules correlates with the inability of axons to regenerate into the dorsal root entry zone after postnatal 3.

Effect of Glia-Associated Proteoglycans on Neurite Outgrowth

In order to determine whether the expression of these particular molecules in areas of gliosis was directly involved in inhibiting neurite outgrowth, filters were implanted at various ages and then removed from the cortex, placed in culture, and used as a substrate for dissociated chick retinal ganglion cells (McKeon et al., 1991; McKeon and Silver, 1992). Prior to seeding these neurons, filters were treated with protease-free chondroitinase ABC in order to digest the GAG side chains linked to the core protein. After 2 days, neurite length was measured and compared to the length of neurites on untreated filters. When neuritic lengths were compared between treated and untreated filters removed from 30-day-old animals implanted as neonates, no differences were found, consistent with the limited expression of proteoglycans in young animals. In contrast, a significant increase in the amount of neurite outgrowth occurred on treated versus untreated filters removed from the cerebral cortex of adult animals 30 days postimplantation. Interestingly, the removal of an inhibitory component of the glial scar by chondroitinase ABC digestion results in an increased amount of neurite outgrowth by unmasking growth-promoting ECM, that is, laminin. Specifically, when neurons seeded on chondroitinase-treated filters are grown in the presence of antibodies to the $\beta1,\beta2$ chains of laminin neurite outgrowth is again significantly reduced when compared to the amount of outgrowth that occurs on chondroitinase treated filters alone (McKeon et al., 1994). These experiments demonstrate that the expression of certain CS-PGs can result in a dramatic decrease in neurite outgrowth on an astrocytic substrate by interacting with ECM molecules. The mechanism of this interaction is not yet clear, but may be due to the highly negative charge of the sulfated proteoglycan, stearic hinderance, or binding to an as yet unidentified receptor. Finally, these data are consistent with a recent report on the expression of both HS-PG and CS-PG following kainic acid-induced gliosis in the hippocampus (Bovolenta et al., 1993). When membranes isolated from injured versus uninjured hippocampi were used as a substrate for neurite outgrowth, significantly less outgrowth occurred on the injured membranes. Neurite outgrowth was improved following treatment of the inhibitory membranes with either heparinase or chondroitinase. The change in neurite outgrowth was greater following heparinase treatment, suggesting that HS-PG was the major inhibitory PG in this system.

WHAT IS THE STIMULUS FOR THE ONSET OF FUNCTIONALLY REACTIVE GLIOSIS?

Stimulation of Astrocyte-Associated Proteoglycan Deposition by β-Amyloid in an In Vitro *Model of Alzheimer's Disease and After Cortical Injury*

In addition to the intense glial response seen after CNS injury, reactive gliosis has also been suggested to be a normal consequence of aging (Duffy et al., 1980; Mancardi et al., 1983) and may play a role in the development of pathologic lesions in Alzheimer's disease (Frederickson, 1992). This hypothesis stems from the observation that there are increased numbers of intensely GFAP-positive glia associated with β-amyloid containing senile plaques as opposed to the number of glia around presenile plaques in the brains of adult humans and aged animals without dementia (Duffy et al., 1980; Nieto-Sampedro, 1987). In fact, it has been suggested that interactions between astrocytes and β-amyloid-containing plaques may be triggered by continued β-amyloid deposition (Mandybur and Chuirazzi, 1990). Finally, since various sulfated proteoglycans have been found to be associated with β-amyloid fibrils (Young et al., 1989; Snow et al., 1992), it has recently been suggested that reactive glia may be contributing to senile plaque formation through interactions via these extracellular matrix components (Canning et al., 1993).

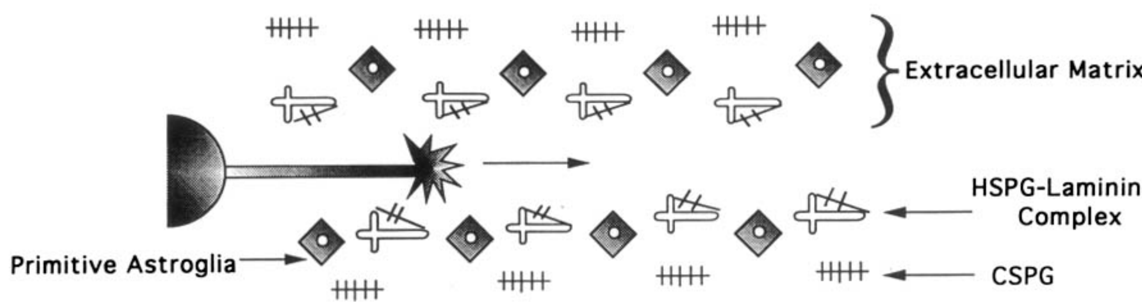
In order to test whether β-amyloid can induce functionally reactive (i.e., growth inhibitory) gliosis, Canning et al. (1993) cultured cortical neurons or astrocytes on synthetic peptides of the amino acid sequence of the β-amyloid molecule, which had been immobilized to a nitrocellulose substrate. Neurons adhered preferentially to peptides containing the 1-40 amino acid sequence rather than the surrounding laminin substrate. Furthermore, it was determined that this affinity was most likely due to the 25-35 amino acid sequence of the β-amyloid molecule.

In contrast to neuronal adhesion, cortical astrocytes, when placed in culture, initially did not show any preference for the various peptides used versus laminin. However, astrocytes on the surfaces of the 1-40 and 25-35 amino acid peptides were highly motile in relation to cells that had attached away from the β-amyloid peptide spot. The glial response was considered specific for the 1-40 sequence, since neither the 1-28 sequence nor scrambled peptides caused any reactive effects. Consistent with the hypothesis that astrocytes may interact with β-amyloid by depositing extracellular proteoglycans, Canning et al. (1993) next stained peptide spots that had been "conditioned" by astrocytes for up to 14 days. With time, there was an increasing amount of a CS-PG deposited both on and around the circumference of the peptide spot. Significantly, when cortical neurons were seeded onto the glial conditioned β-amyloid spots, they failed to show any adhesive preference, in contrast to their behavior on unconditioned spots, rather tending to adhere in higher numbers to the surrounding laminin. These data suggest that the surface of the peptide had now become an unfavorable substrate for neuronal attachment, due possibly by the deposition of proteoglycans by "reactive" astroglia.

The observation that exposure to specific amyloid peptides can induce the deposition of CS-PG *in vitro* is supported by recent *in vivo* evidence (Canning et al., 1993). When Millipore filters are implanted into the cortex of neonatal animals, there is little CS-PG staining even after 30 days postimplantation (McKeon et al., 1991). However, when β-amyloid-containing filters are implanted into neonates, there is a dramatic increase in the amount of CS-PG staining after 30 days, suggesting that glia within the cortex of young animals respond to the presence of amyloid by depositing increased amounts of CS-PG. This is consistent with a number of recent reports that have demonstrated a rapid appearance of β-amyloid precursor protein (APP) associated with reactive astrocytes after cortical injury in adult animals (Siman et al., 1989; Kawarabayashi et al., 1991; Otsuka et al., 1991), where there is also increased deposition of CS-PG (McKeon et al., 1991). Whether neonatal animals respond to trauma by depositing β-APP is not known. Finally, the above data, along with the finding that CS-PG is associated with astrocytes localized at the periphery of senile plaque cores in the brains of human patients with confirmed Alzheimer's disease (Canning et al., 1993), lend support to the hypothesis that β-amyloid may act as a general trigger for reactive gliosis in the CNS. This stimulus may result in the deposition of a variety of molecules inhibitory to axon outgrowth and survival and thus may play a role in the onset of this, and possibly other, neurodegenerative diseases.

TOWARD A THEORY OF NEURON/GLIAL CELL INTERACTIONS MEDIATED BY EXTRACELLULAR MATRIX MOLECULES

It is now evident that astroglia have many different functions within the CNS during development and in adult animals (Figure 27–1). These functions include expressing various cell or substrate adhesive



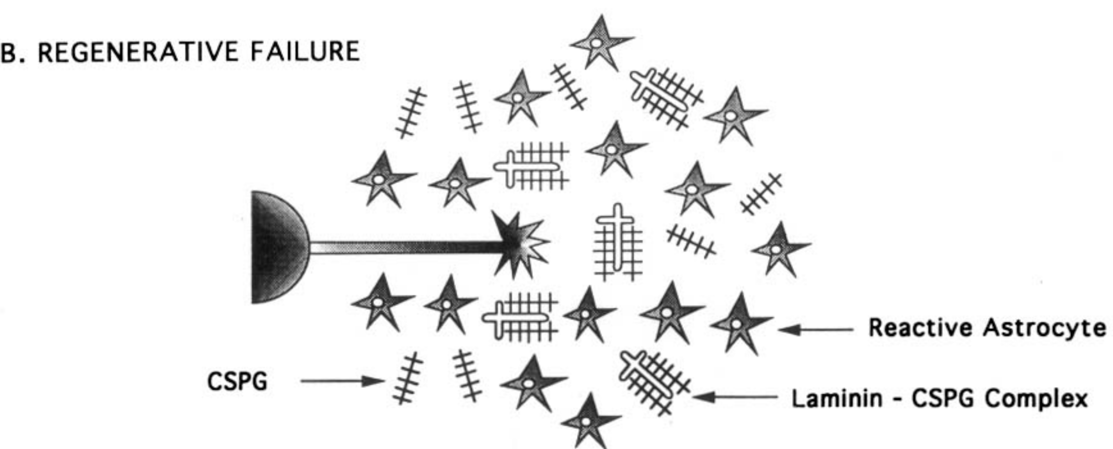


FIG. 27-1. Possible role of glial-derived extracellular matrix in neurite outgrowth during development and regenerative failure. **(A)** In certain regions during development, pioneering neurites may grow along preformed pathways of neuroepithelial cells, which later develop into astroglia. These primitive glia deposit laminin as part of the surrounding extracellular matrix (ECM). In addition to laminin, these cells express cell adhesion molecules (e.g., N-CAM and N-cadherin) on their surface. The combined expression of these growth-promoting molecules may help to direct growing neurites to specific regions of the developing brain. When complexed with heparan sulfate proteoglycan (HS-PG), the neurite growth-promoting capability of laminin is significantly increased. Alternatively, other proteoglycans, that is, chondroitin sulfate proteoglycan (CS-PG) and keratan sulfate proteoglycan, may form barriers to growing neurites in areas of the ECM surrounding these pathways, thus helping to direct neurite outgrowth by restricting the areas where neurites can grow. **(B)** During disease or after trauma to the CNS, astrocytes react by proliferating in a disorderly fashion around the area of damage. The density of reactive astrocytes has been suggested to form a physical barrier to regenerating axons. Also associated with the astrocytic response to injury is the increased deposition of CS-PG within the ECM. The increased expression of this putative growth inhibitory proteoglycan has been implicated as one reason for the failure of damaged axons to regenerate. However, the expression of growth promoting ECM molecules, specifically laminin, is also increased on the surface of the reactive glia, as well as part of the reestablished basal lamina. In this model, CS-PG may complex with laminin and limit its accessability to regenerating axons, thereby forming a molecular barrier to growing neurites. Removal of the CS glycosaminoglycan side chains from the native proteoglycan results in an increased amount of neurite outgrowth. This change in neurite outgrowth is reflective of an increased accessability to laminin, since it can be blocked by antilaminin antibodies. Thus, CS-PG may inhibit regenerating axons directly by serving as a poor substrate for neurite outgrowth or indirectly by complexing with trophic factors or growth promoting ECM molecules, limiting the accessability of these substances to regenerating axons.

molecules along pathways of developing axon tracts. Alternatively, certain populations of astrocytes can express other extracellular matrix molecules, whether during development, after injury, or during degenerative diseases, that are inhibitory for axon outgrowth. The best examined of these inhibitory molecules are the family of PGs, specifically chondroitin sulfate-containing PGs. However, the specific mechanism by which CS-PG inhibits neurite outgrowth is still unclear, although it is likely that they interact with ECM molecules and attenuate their growth-promoting properties.

Aside from inhibiting neurite outgrowth *in vitro* and being present in barrier areas *in vivo,* PGs are known to interact with ECM molecules. For example, heparan sulfate-proteoglycan (HS-PG) promotes neurite outgrowth by complexing with laminin (Dow et al., 1991), in contrast to the proposed in-

teractions between laminin and CS-PG. Thus, while the number and diversity of the proteoglycans in the CNS is only recently becoming clear (Herndon and Lander, 1990), it is likely that many of these PGs are involved in different functions during development and/or regenerative failure. One possibility is that the interaction between neurons and glia is mediated by the combined expression of each of these molecules, both growth-promoting and growth-inhibitory. While each of these molecules may affect axon outgrowth in a specific manner when used in isolation, because of the interaction between these different types of molecules, the final amount of neurite outgrowth that occurs after injury or during disease may be determined by the predominant type or amount of growth-promoting versus growth-inhibitory molecules ultimately expressed. Thus, for example, CS-PG may inhibit neurite outgrowth after injury directly by influencing the ability of axons to grow, but also indirectly by complexing with both growth-promoting ECM and trophic molecules, making them less available to growing neurites. Whatever the mechanism, increasing our knowledge of the specific surface and extracellular matrix molecules associated with astroglia will enhance our understanding of the role these cells and molecules play during development and pathological conditions.

28 Tenascin and janusin: glial recognition molecules involved in neural development and regeneration

ANDREAS FAISSNER and MELITTA SCHACHNER

NEURAL EXTRACELLULAR MATRIX GLYCOPROTEINS CONTRIBUTE TO THE REGULATION OF NEUROHISTOGENESIS

The development of the central nervous system (CNS) of vertebrates unfolds as a finely tuned sequence of specifiable steps. Several key events have been distinguished, namely, proliferation of epithelial stem cells, emigration of neuronal precursors from the ventricular zone to their final destination, formation of neuronal aggregates—the future nuclei—and of neuronal layers, establishment of neuronal projections to targets of innervation, neuronal cell death, and, finally, pruning and rearrangement of processes. These developmental events are subject to a tight network of regulatory mechanisms involving specific intercellular, membrane-mediated interactions, the presence of limiting amounts of growth factors and electrical activity of the nervous tissue (for review see Jacobson, 1991). It is well established that the interplay of neurons with glia plays a pivotal role in this context. For example, there is evidence that glial cells are critically involved in the guidance of migrating neuronal precursors and of extending neuronal fiber projections (see Chapter 49) and in the segregation of forming neuronal aggregates and nuclei (see Chapter 27 and below). Cell adhesion molecules and components of the extracellular matrix (ECM) mediate, at least in part, neuron-glia interactions. The majority of cell adhesion molecules hitherto described in the nervous system can be assigned to growing gene families, for example, the cadherin superfamily for the calcium-dependent and the immunoglobulin superfamily for the calcium-independent adhesion mechanism (Jessel, 1988; Rathjen and Jessell, 1991; Schachner, 1991; Takeichi, 1991). Furthermore, ECM components like laminin, fibronectin, or proteoglycans and integrin-type receptors are expressed in developing neural tissues (Sanes, 1989; Reichardt and Tomaselli, 1991). There is increasing awareness that, in addition to conducive, adhesive interactions, antiadhesive, inhibitory, and/or repulsive influences are of importance for the generation of ordered neural structures (Patterson, 1988; Keynes and Cook, 1992). Indeed, membrane-bound inhibitors have been described and are implicated in development and in degeneration and regeneration phenomena (see Chapters 27, 57, and 60). Also, a growing family of extracellular matrix glycoproteins, originally called J1 (Kruse et al., 1985), has been discovered in developing neural tissues which are of particular interest because they seem to embody both inhibitory and stimulatory properties for neuronal differentiation. Systematic study of these molecules might therefore deepen our understanding of cellular mechanisms underlying both growth and avoidance behaviors.

J1 COMPRISES TENASCIN AND JANUSIN

The J1 family of molecules was discovered as a constituent of the "rest-L2" fraction of L2/HNK-1-positive glycoproteins purified from detergent extracts of adult mouse CNS tissues. Polyclonal antibodies to a prominent 160 kD component of "rest-L2" react in Western blot experiments with four major components of 160 kD, 180 kD, 200 kD, and 220 kD apparent relative molecular mass (M_r), which show differential expression during CNS development. J1-200/220 is expressed during embryonal and early postnatal stages of development, while J1-160/180 reaches higher expression levels after birth and persists into adulthood. Immunoprecipitation studies demonstrated that J1-200/220 is produced by astrocytes *in vitro* (Kruse et al., 1985; Faissner et al., 1988). Polyclonal J1-antibodies interfere with the binding of granule cell neurons to astrocyte surfaces in a short-term *in vitro* assay (Keilhauer et al., 1985), suggesting that J1-200/220 mediates neuron-astrocyte interactions (Kruse et al., 1985). Subsequent systematic immunochemical

studies led to the conclusion that the J1-molecules consist of two independent entities, the pairs of glycoproteins J1-160/180 and J1-200/220, which contain small, but immunologically detectable homologies. J1-200/220 is the mouse homologue of tenascin, a growing family of extracellular matrix molecules (Faissner et al., 1988). J1-160/180 has been renamed janusin and constitutes an independent class of extracellular matrix glycoproteins (Pesheva et al., 1989, 1993; Fuss et al., 1993). The putative homologue of mammalian janusin in the chicken has been termed *restrictin* (Rathjen et al., 1991; Nörenberg et al., 1992). Increasing evidence suggests that both janusin and tenascin play a crucial role in mediating glial influences on neuronal and glial cell behavior.

TENASCIN GLYCOPROTEINS REPRESENT A DISTINCT GENE FAMILY OF EXTRACELLULAR MATRIX COMPONENTS

Tenascin glycoproteins of the ECM (Chiquet-Ehrismann et al., 1986) have been independently discovered by several groups and named myotendinous antigen (Chiquet and Fambrough, 1984a, 1984b), human glioma-mesenchymal extracellular matrix (GMEM) antigen (Bourdon et al., 1983, 1985), hexabrachion (Erickson and Inglesias, 1984; Erickson and Taylor, 1987), cytotactin (Grumet et al., 1985), J1-200/220 (Kruse et al., 1985, Faissner et al., 1988), J1/tenascin (Faissner and Kruse, 1990), and polypeptide 150/225 (Gulcher et al., 1986), and will be referred to as tenascin in this chapter. Tenascin is transiently expressed in developing organs such as the CNS (Kruse et al., 1985, Grumet et al., 1985, Gulcher et al., 1986), the kidney (Aufderheide et al., 1987), the intestine (Aufderheide and Ekblom, 1988), and the mammary gland (Chiquet-Ehrismann et al., 1986), to name just a few (reviewed in Erickson and Bourdon, 1989). In most of these cases, tenascin is confined to circumscribed areas in a "site-restricted" fashion, for example, to areas of epithelial-mesenchymal induction (Crossin et al., 1986). Primary derived amino acid sequences have been reported for chicken (Jones et al., 1989; Spring et al., 1989), mouse (Saga et al., 1991; Weller et al., 1991), and human tenascin (Gulcher et al., 1989, Siri et al., 1991). The glycoproteins comprise a cysteine-rich segment at the amino terminus, subsequent 13½ epithelial growth factor (EGF)-type repeats in the chicken and 14½ EGF-type repeats in mouse and human, followed by eight fibronectin type III (FNIII) homologous repeats and homologies to fibrinogen β and γ at the carboxyl terminus. Several isoforms have been described, which contain alternatively spliced FNIII repeats between the fifth and the sixth FNIII repeat of the basic structure. The interspecies homology between additionally inserted analogous FNIII repeats reaches 90%, while the intraspecies homology between FNIII modules is around 40%. Theoretically, a wealth of tenascin isoforms could potentially be encoded by various combinations of alternatively spliced FNIII repeats, but only a restricted number has hitherto been described in the mouse (Figure 28-1). Biochemically, tenascin glycoproteins display apparent molecular weights ranging from 190 kD to 320 kD and are linked to multimers by disulfide bridges at the amino terminal end (Chiquet-Ehrismann et al., 1986; Aufderheide et al., 1987; Taylor et al., 1989; Faissner and Kruse, 1990). The prevalent configuration of native tenascin is a hexamer, which appears as six-armed structure, a so-called hexabrachion, upon rotary shadowing and electron microscopy (Erickson and Inglesias, 1984, Vaughan et al., 1987). The apparent molecular mass of the hexabrachion is about 1000 kD, and it sediments with 6 S in glycerol gradients (Taylor et al., 1989). Tenascin glycoproteins from CNS tissues express the L2/HNK-1 carbohydrate epitope, in contrast to the mesenchymally derived glycoprotein (Kruse et al., 1984, 1985; Chou et al., 1986; Probstmeier et al., 1990).

TENASCIN IS A COMPONENT OF TRANSIENT CENTRAL NERVOUS SYSTEM BOUNDARIES

In the developing chicken, tenascin is first visible at the gastrula stage. Subsequently, it appears in the basement membrane of the developing neural tube and notochord and its expression unfolds as cephalocaudal gradient in a defined temporal sequence (Crossin et al., 1986). At later stages tenascin is detectable in distinct areas of the developing CNS where its expression generally correlates with key events of neurohistogenesis like neuronal migration, segregation of neuronal assemblies, and extension of neuronal processes (Crossin et al., 1986; S. Bartsch et al., 1992; U. Bartsch et al., 1992). Although tenascin-immunoreactivity has also been detected on the surface of neurites most neuronal cell types do not express the glycoprotein by themselves. *In situ* hybridization studies have clearly established astrocytes as the preeminent source of tenascin in the developing brain (Prieto et al., 1990; S. Bartsch et al., 1992; Tucker, 1991; 1993; Tucker et al., 1993). In addition, tenascin transcripts have been reported in the ependymal layer of postnatal mice (Tucker et al., 1993) and in a minority of avian retina neurons

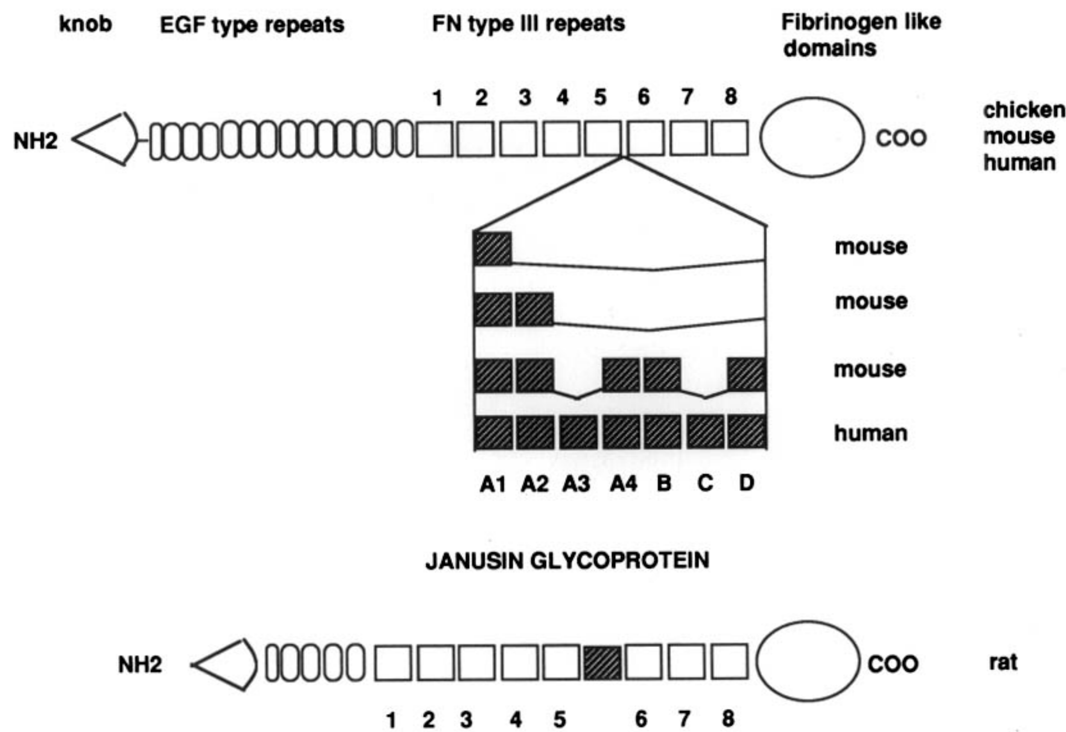

FIG. 28-1. Isoforms of tenascin. A summary of the known isoforms of mouse tenascin. The basic variant of the glycoprotein consists of a cysteine-rich amino terminus, a series of EGF-type repeats, 8 fibronectin type III (FNIII) homologous repeats (numbered 1 through 8) and homologies to fibrinogen β and γ at the carboxyl terminus in chicken, mouse, and human. The isoforms of mouse tenascin are generated by alternative splicing of additional repeats between FNIII module 5 and 6 of the smallest form. These are positioned according to the highest degree of homology with analogous motives of human tenascin, where 7 additional FNIII repeats have been discovered in the largest known isoform (designated *A1–A4*, *B*, *C*, and *D* following the suggestion of Aukhil et al., 1993). The scheme is based on sequence data published in the literature (Jones et al., 1989; Spring et al., 1989; Gulcher et al., 1989; Saga et al., 1991; Weller et al., 1991). Theoretically, a large number of variants is conceivable. For example, 7 distinct isoforms could be created with one additional FNIII repeat. It is currently unknown whether this potential is realized *in vivo*. The M_r's of the glycoproteins range from 190 for the smallest variant to 320 for the largest isoform described in humans (Erickson and Bourdon, 1989). For further details see text.

(Tucker, 1991). Analysis of the differential distribution of transcripts for tenascin isoforms as compared to the basic, nonalternatively spliced variant has revealed a correlation of the expression of the high M_r forms with events of cell proliferation, cell migration, and process outgrowth (Tucker, 1993). It had been noted that prospective functional neurophysiological processing units are transiently demarcated by glial cells during cortical development. These glial boundaries could be visualized with the lectin PNA whose binding site displays a locally restricted expression, for example, in the somatosensory barrel field (Steindler and Cooper, 1987; Cooper and Steindler, 1986a, 1986b). Recently, the discovery that tenascin immunoreactivity colocalizes with the lectin in several cases and transiently delineates barrels during the period of thalamocortical afferent ingrowth has considerably advanced our knowledge about the molecular composition of boundaries in neural tissues (Crossin et al., 1989, 1990; Steindler et al., 1989a, 1989b, 1990; Steindler, 1993) (Figure 28-2). Tenascin glycoproteins from postnatal mouse brain, however, do not display a PNA-binding site. In fact, the glial boundaries in the somatosensory cortex contain additional molecular components which colocalize with tenascin in these areas, such as the PNA-binding chondroitin sulfate proteoglycan CTBP (Crossin et al., 1989). Discrete distribution of tenascin glycoproteins has also been detected in other areas of the developing nervous

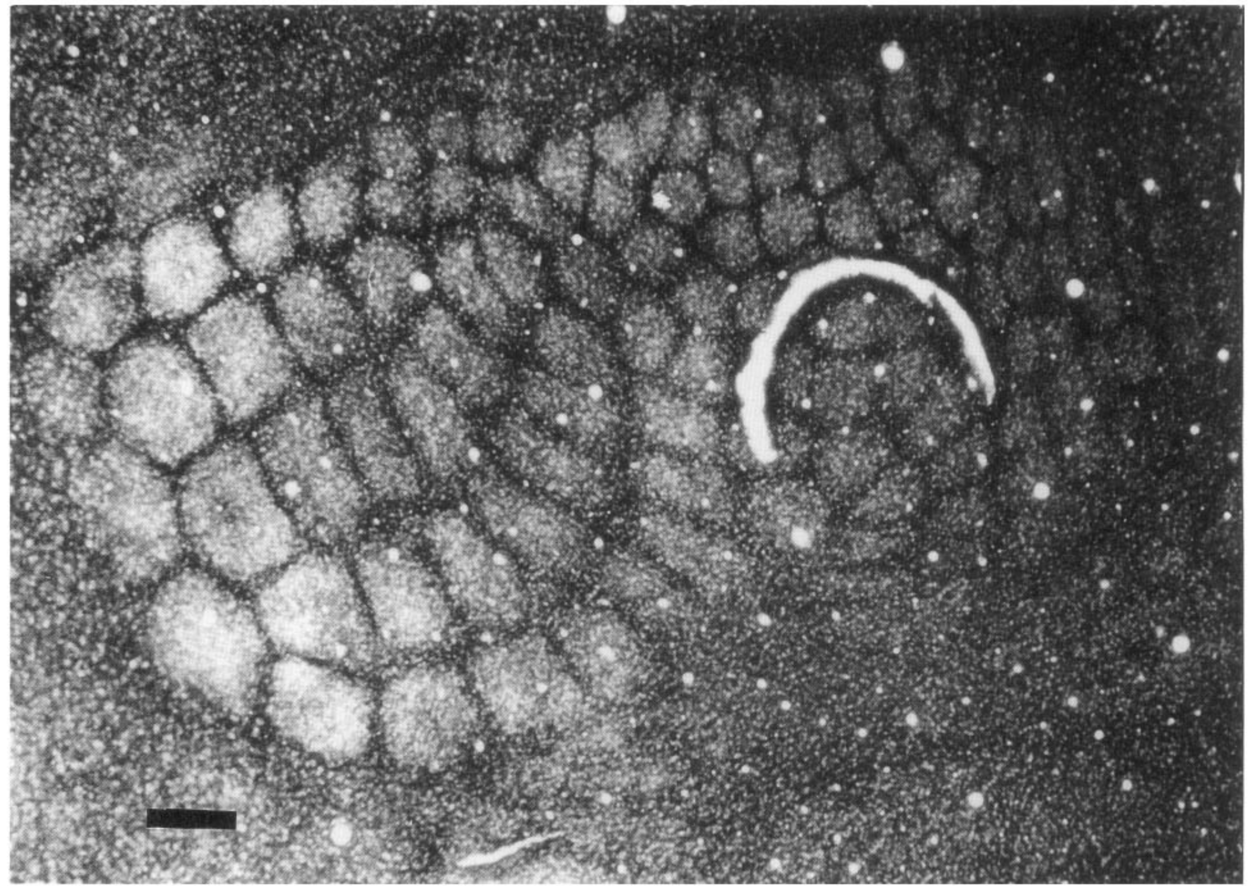

FIG. 28-2. Expression of tenascin glycoproteins in the somatosensory cortex. Top view of a flattened tangential section from postnatal day 6 somatosensory cortex of the mouse. Tenascin distribution was revealed by polyclonal antitenascin and peroxidase-derivatized anti-rabbit antibodies. Note that tenascin depositions delineate the boundaries of future barrels in the somatosensory barrel field. Bar: 200 μm. [This figure was generously provided by Dr. D. A. Steindler.]

system. For example, tenascin depositions follow the subdivision between patch and matrix compartments of the forming striosome or of fiber tracts in the internal capsule and separate functional compartments in nuclei of the brainstem, for example, the trigeminal nucleus (Steindler et al., 1990; Laywell and Steindler, 1991; O'Brien et al., 1992; Steindler, 1993), and tenascin boundaries have also been described in the forming peripheral nerve (Martini and Schachner, 1991). In all of these cases, the expression of tenascin is transient, and the glycoproteins are virtually undetectable in most of the adult, mature mouse CNS and PNS structures. In contrast, tenascin could still be detected in several adult CNS regions such as cerebellum, olfactory bulb, retina, and hippocampus (Miragall et al., 1990; S. Bartsch et al., 1992; U. Bartsch et al., 1992, 1993; U. Dörries and M. Schachner, unpublished observations). In addition, a persisting boundary of tenascin-immunoreactivity has, for instance, been revealed in the optic nerve head (U. Bartsch et al., 1994). Interestingly, this structure is believed to prevent immigration of oligodendrocyte precursors into the nonmyelinated retina (Small et al., 1987). It should be mentioned here that tenascin expression, however, is not discrete in all parts of the CNS at any stage of neural development. For example, rather uniform distribution of tenascin has been reported in places and at times of extensive axon outgrowth in mouse cerebellum (S. Bartsch et al., 1992), in mouse optic tectum (S. Bartsch, U. Bartsch, and M. Schachner, unpublished observations), in mouse cortex prior to and during thalamocortical afferent ingrowth (Godfraind et al., 1988; Jhaveri et al., 1991; Sheppard et al., 1991), and in the adult regenerating mouse sciatic nerve (Daniloff et al., 1989, Martini et al., 1990). Thus, both neuronal cell bodies and axonal growth cones seem able to cruise through homogeneous tenascin-containing territories *in vivo*.

TENASCIN EXPRESSION IS REGULATED BY VARIOUS FACTORS

The factors that regulate the timing and the topography of tenascin expression are only partially known. The tenascin gene promoter contains a functional binding site for the homeobox transcription factor Evx-1 and an AP-1/(TRE) site, which may be activated by cellular signal transduction events (Jones et al., 1990, 1992). Several growth factors have been reported to stimulate tenascin expression, for example, TGF-β1, NGF, bFGF, and angiotensin II, which enhance tenascin expression in embryonic fibroblasts, C6 glioma, Swiss 3T3 cells (a fibroblastoid cell line), and vascular smooth muscle cells, respectively (Pearson et al., 1988; Yavin et al., 1991; Sharifi et al., 1992; Tucker et al., 1993). In the case of 3T3 cells, bFGF preferentially induces the high M_r isoforms on both the protein and the message levels, while TGF-β increases the expression of the 190 kD basic variant (Tucker et al., 1993). In the somatosensory barrel field, the appearance of tenascin boundaries is concomitant or consecutive to the ingrowth of thalamocortical projections. The hollowing out of tenascin immunoreactivity in the barrel field might indicate that the tenascin boundaries in this area are sculptured by afferent fiber systems (Jhaveri et al., 1991; Steindler et al., 1989b). The dependence of boundary formation on neuronal afferents in striosomes has been experimentally demonstrated by selective lesioning of the nigrostriatal pathway (O'Brien et al., 1992). Consistent with these observations recent data show that fibers growing out from retinal explants induce downregulation of tenascin in astrocyte monolayers *in vitro* (Ard et al., 1993). The neuronal factor(s) presumably responsible for the establishment of tenascin patterns and the role of neuronal activity are as yet unknown. Finally, interspecies comparison has shown that the regulation of tenascin expression displays a certain degree of malleability during phylogeny. For example, human adult metencephalon does not show tenascin immunoreactivity, while bovine adult metencephalon displays substantial levels of the molecule (Rettig et al., 1992).

JANUSIN GLYCOPROTEINS BELONG TO THE SAME GENE FAMILY AS TENASCIN

Janusin, originally the J1-160/180 constituent of the J1 family of molecules (which is comprising tenascin and janusin glycoproteins), is a further member of the tenascin gene family (Erickson, 1993b) expressed in neural tissues and consists of two major glycoproteins of 160 kD and 180 kD apparent M_r (Kruse et al., 1985; Faissner et al., 1988; Pesheva et al., 1989; Morganti et al., 1990). Janusin immunochemically shares some epitopes with tenascin but represents a clearly distinct entity (Faissner et al., 1988; Pesheva et al., 1989), as underlined by the analysis of janusin cDNA sequences. Janusin consists of a cysteine-rich amino-terminal region followed by 4½ EGF-type repeats and nine FNIII repeats. The sequence is completed by homologies to fibrinogen β and γ. It is presently not known whether the isoforms of 160 kD and 180 kD are generated by alternative splicing of FNIII repeats (Fuss et al., 1993). The homology to tenascin FNIII repeats is about 70% at corresponding positions, underscoring the relatedness of both glycoproteins (Fuss et al., 1991, 1993) (Figure 28-1). In purified form both janusin and restrictin express the L2/HNK-1 epitope and form multimers under non-reducing conditions (Pesheva et al., 1989; Nörenberg et al., 1992). In particular, trimers and some mono-, di-, and tetramers have been observed for restrictin while the 160 kD and 180 kD forms of janusin form mainly mono- or dimers and trimers, respectively (Pesheva et al., 1989; Nörenberg et al., 1992). In the appropriate ionic milieu janusin assembles to large aggregates of interacting units which may be important in the context of myelinogenesis (Pesheva et al., 1991). Consistent with this view, janusin is expressed by oligodendrocytes at the onset of myelination (Pesheva et al., 1989, Wintergerst et al., 1993), where it possibly is involved in the wrapping of myelin loops in a self-binding mechanism (Pesheva et al., 1991). In myelin of young and adult animals, janusin remains detectable at nodes of Ranvier (ffrench-Constant et al., 1986), where it appears to mark a "microbarrier," interrupting the longitudinal expansion of myelin sheeths at the sites where axons, myelin, and astrocytes meet. Interestingly, a recent study has revealed that astrocytes or astrocyte-conditioned culture supernatants, PDGF and bFGF enhance expression of janusin on more differentiated, O1- and O10-positive oligodendrocyte surfaces, while dorsal root ganglia or spinal cord neurons induce janusin downregulation from both mature oligodendrocytes and their progenitors (Jung et al., 1993). It is noteworthy that Schwann cells, the myelin forming cells of the peripheral nervous system, do not express janusin at any developmental stage. It has therefore been speculated that the presence of janusin in myelin of the CNS and its absence in the PNS may be related to the capacities of axons to regenerate after infliction of a lesion in adult mammals. Finally, janusin protein and mRNA have been demonstrated in subpopulations of neurons in the central nervous

system (Rathjen et al., 1991; Fuss et al., 1993). The functional implications of janusin expression by certain types of neurons is, however, presently unknown.

TENASCIN AND JANUSIN DISPLAY REPULSIVE PROPERTIES FOR CENTRAL NERVOUS SYSTEM NEURONS

The distribution of tenascin in boundary-like structures that separate anatomically defined, functional processing units of the nervous system could indicate that it serves to segregate assembling neuronal modules from each other in these areas. Several *in vitro* studies support this hypothesis. Notably, tenascin glycoproteins *per se* are a bad substrate for neural cell culture. In fact, embryonic day (E)10 chicken neurons or glial cells fail to attach to tenascin when plated under normal gravity conditions and E11 chicken sympathetic, E14 rat mesencephalic, E18 rat hippocampal or postnatal day 6 mouse cerebellar neurons and E14 mouse cerebral astrocytes do not form monolayer cultures when the cells are plated on tenascin substrata and maintained for 24 hours *in vitro* (Friedlander et al., 1988; Faissner and Kruse, 1990; Wehrle and Chiquet, 1990). Rather than providing a favorable environment for neural cells, tenascin displays repulsive properties. For example, tenascin mixed with polyornithine induces neuronal aggregate formation and neurite fasciculation under high-density plating conditions of several types of embryonic and postnatal CNS neurons (Faissner and Kruse, 1990). Tenascin also induces the fasciculation and reduces the branching of neurites leaving E3 chicken spinal cord explants *in vitro* (Wehrle and Chiquet, 1990). Likewise, postnatal day 6 cerebellar neurons form less dense and aggregating cultures on mixed janusin-laminin substrates as compared to laminin alone (Pesheva et al., 1989). The induction of cell aggregation and neurite fasciculation on homogeneous tenascin-containing substrates could indicate that the adhesion forces between cell bodies and/or neurites and the culture substrate are reduced. Consistent with this interpretation, it has been documented that tenascin reduces the surface covered by the cell body *in vitro* in several cases. This so-called "antispreading effect" is paralleled by a reduction of the number of focal adhesion points which are believed to constitute the attachment sites of cells to their growth surface (Burridge et al., 1988). Antispreading effects of tenascin have been reported for both neural and nonneural cells, such as rat or mouse E18 hippocampal neurons (Lochter et al., 1991), mouse E11 fibroblast and mouse L929 cells (Chiquet-Ehrismann et al., 1988), neural crest cells (Tan et al., 1987; Epperlein, 1988; Mackie et al., 1988), mesodermal cells from gastrula stage embryos (Riou et al., 1990) and human melanoma cells (Halfter et al., 1989). The antispreading properties of tenascin are also observed when tenascin is combined with fibronectin, laminin, and polycations and is clearly documented when the cells are grown in the presence of tenascin added as soluble component to the culture medium rather than as component to the culture substrate (Tan et al., 1987; Chiquet-Ehrismann et al., 1988; Mackie et al., 1988; Faissner and Kruse, 1990; Riou et al., 1990; Lochter et al., 1991). Recently, also laminin and merosin, extracellular matrix molecules that possess binding sites for neuronal cell bodies and growth cones (Sanes, 1989; Reichardt and Tomaselli, 1991), have been assigned repulsive properties for olfactory neurons (Calof and Lander, 1991). Repulsive properties of extracellular matrix molecules might be required to regulate the strength of cellular interactions with the pericellular environment. Release of binding forces could be helpful for cell detachment, movement, and motility, and this might be the prominent biological function of components like tenascin, janusin, osteonectin/sparc, and thrombospondin, which display antiadhesive qualities in several nonneural tissue systems (reviewed in Sage and Bornstein, 1991; Chiquet-Ehrismann, 1991).

These repulsive and antispreading properties of tenascin glycoproteins are presumably mediated by cell binding site(s) in the molecule and complementary receptors at the surface of responsive cells. Indeed, erythrocytes, postnatal day 6 mouse cerebellar and E9 chicken retina neurons, E10 chicken embryo fibroblasts, mouse L929 and U251MG human glioma cells attach to tenascin in *short-term* cell-binding assays (Grumet et al., 1985; Kruse et al., 1985; Chiquet-Ehrismann, 1986; Friedlander et al., 1988; Bourdon and Ruoslahti, 1989; Nörenberg et al., 1992). Similarly, oligodendrocytes were found to interact with janusin in short-term adhesion assays (Morganti et al., 1990). It has therefore been proposed that initial cell binding to tenascin glycoproteins is required to trigger the antispreading or repulsion event in responsive cells, implying a two-step model of cell-tenascin or -janusin interactions. Initial recognition events could lead to downstream processes which, among others, perhaps involve cytoskeletal rearrangements (Lotz et al., 1989; Morganti et al., 1990; Murphy-Ullrich et al., 1991; Crossin, 1991; Faissner, 1993). At least three cell binding sites have been assigned to different FNIII and the fibrinogen-like domains of tenascin with the help of cDNA-de-

rived fusion proteins and/or monoclonal antibodies. These domains can be distinguished from areas presumably responsible for the antispreading and/or repulsive properties (Spring et al., 1989; Bourdon and Ruoslahti, 1989; Murphy-Ullrich et al., 1991; Prieto et al., 1992; Aukhil et al., 1993; Joshi et al., 1993; Sriramarao et al., 1993) (Figure 28-3).

The repulsive properties of tenascin are even more pronounced when the cells are exposed to patterned substrates. On these patterned substrates regions containing tenascin combined with a component supportive for cell attachment and differentiation such as the polycation poly-DL-ornithine or the ECM glycoproteins laminin or fibronectin alternate with areas covered with these latter components only. This design permits to monitor whether cells in choice situations are attracted to or dispersed from tenascin on the surface of a culture dish or coverslip. Under these conditions, embryonic and postnatal CNS neurons preferentially grow on tenascin-free parts of patterned tenascin/polyornithine coverslips (Faissner and Kruse, 1990). Likewise, neurites growing out from embryonic chicken dorsal root ganglion (DRG) explants avoid tenascin- or janusin-containing areas of patterned substrates constructed with laminin or fibronectin (Crossin et al., 1990; Taylor et al., 1993). The repulsive properties of tenascin *in vitro* are consistent with the possibility that these glycoproteins might separate neuronal assemblies and emerging fiber tracts *in situ*. Repulsive effects of tenascin have also been observed in neuron-glia cocultures where so-called "rocky" astrocytes produce circumscribed, locally enriched patches of tenascin, which deflect neurons and neurites (Grierson et al., 1990).

TENASCIN AND JANUSIN IN THE CONTROL OF NEURITOGENESIS

Despite their repulsive and/or antiadhesive effects on various cell types including neurons and their processes, also supportive roles of tenascin and/or janusin for histogenetic events have been documented. Thus, tenascin glycoproteins are thought to promote migration of mesodermal cells in amphibian gastrulation, of dispersing neural crest cells and their derivatives, for example, prospective corneal epithelia, and of granule cell neurons translocating from the external to the internal granule cell layer during cerebellar development (Chuong et al., 1987; Tan et al., 1987; Mackie et al., 1988; Bronner-Fraser, 1988; Riou et al., 1990; Kaplony et al., 1991; Tucker and McKay, 1991; S. Bartsch et al., 1992; Husmann et al., 1992). In the latter case a region presumably implied in granule cell migration could be allocated to

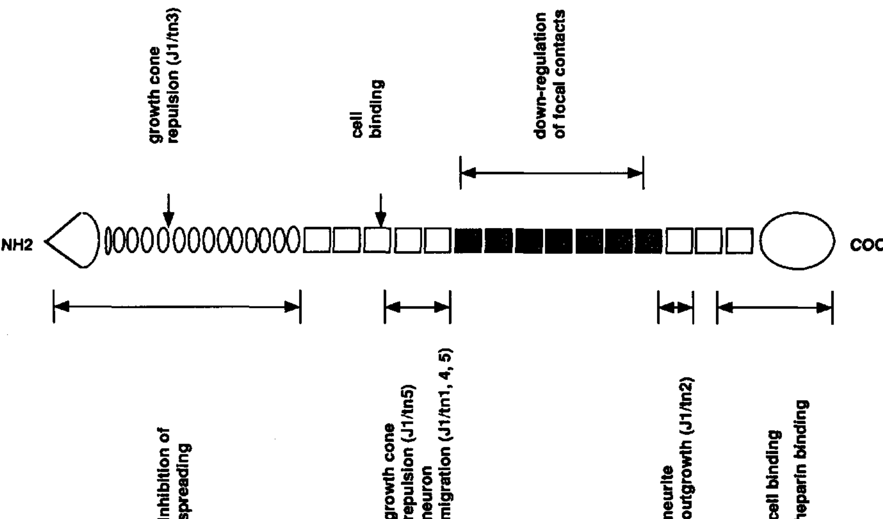

FIG. 28-3. Localization of functional domains of tenascin. Condensed results of several studies on structure-function interrelationships of tenascin glycoproteins. The functional domains are tentatively projected onto the largest known isoform. The map is based on the application of monoclonal antibodies with known binding sites, of fusion proteins produced in bacterial expression systems, and of proteolytic fragments of the glycoprotein in functional *in vitro* assays. The binding sites of the monoclonal antibodies J1/tn1-5 to mouse tenascin, which have been used in various perturbation assays, are indicated in parenthesis, next to the assignment of functional properties to the corresponding domains. For the meaning of the geometrical symbols see Figure 28-1, and for further details see text.

FNIII repeats 3 to 5 proximal of the alternative splice site by use of a panel of monoclonal antibodies in perturbation assays (Husmann et al., 1992) (Figure 28-3). Interestingly, dual, opposite effects of tenascin could also be demonstrated in these systems. Indeed, tenascin-containing substrata inhibit the emigration of satellite cells from E4 to E9 chicken DRG explants (Wehrle-Haller and Chiquet, 1993) and tenascin added as soluble component to the culture medium reduces neurite extension (Crossin et al., 1990, Lochter et al., 1991) and migration rates of neuroblastoma cells (Halfter et al., 1989) *in vitro* on a variety of substrates, for example, laminin and fibronectin. In view of these dual properties, the polarized expression of tenascin in the anterior as compared to the posterior somite during peripheral nervous system development may thus be part of a molecular scaffold involved in positioning neural crest derivatives (Mackie et al., 1988; Stern et al., 1989; Tan et al., 1987, 1991). In addition tenascin glycoproteins also possess neurite outgrowth promoting properties (Wehrle and Chiquet, 1990, Lochter et al., 1991, Husmann et al., 1992, Taylor et al., 1993, Lochter and Schachner, 1993, Wehrle-Haller and Chiquet, 1993). The promoting effect may depend on the developmental stage of the neurons, as shown for chicken DRG where tenascin-containing culture substrata stimulate neurite outgrowth from E4 to E6 and reduce or even inhibit fiber growth from E9 to E10 explants (Crossin et al., 1990; Taylor et al., 1993; Wehrle-Haller and Chiquet, 1993). Neurite outgrowth promotion by CNS neurons involves a region of the FNIII repeats around or downstream of the distal splice site and distinct from domains participating in cell-binding and repulsion (Lochter et al., 1991, Husmann et al., 1992) (Figure 28-3). The roles of tenascin and janusin in both the promotion and the guidance of neurite growth have been investigated in more detail in view of the fundamental importance of this process for the establishment of neuronal connections.

Careful analysis with time-lapse video microscopy has shown that growth cones of DRG and retinal ganglion neurons extending on laminin avoid growing into territories containing janusin and tenascin when confronted with sharp substrate boundaries of these glycoproteins. Thus both janusin and tenascin are repulsive for both peripheral (DRG neuron) and central (retinal ganglion neuron) growth cones which are given the choice between growing on these substrates or not (Figure 28-4). When DRG neuron growth cones are confronted with either janusin or tenascin in no-choice assays in the presence of laminin, they advance more on these substrates at a slightly faster rate than on laminin combined with a control substrate such as BSA. In contrast, retinal ganglion neuron growth cones are unable to advance on janusin- and tenascin-containing substrates in similar assays, which suggests that the ability of janusin and tenascin to promote neurite outgrowth might be cell type specific (Perez and Halfter, 1993; Taylor et al., 1993). Dorsal root and retinal ganglion cell growth cones are likely to encounter both tenascin and janusin during development (Crossin et al., 1986; Pesheva et al., 1989; Martini and Schachner, 1991; U. Bartsch et al., 1992; Wintergerst et al., 1993; U. Bartsch et al., 1993a, 1993b). That janusin is also repulsive for neurites in choice assays and is able to promote neurite outgrowth for at least one neuronal type, when offered as a uniform substrate, underscores the possibility that the structurally closely related glycoproteins janusin and tenascin may function to effect neurite outgrowth by similar mechanisms. The failure of monoclonal and polyclonal antibodies against janusin to neutralize the repulsive properties for advancing growth cones (Taylor et al., 1993) suggests that distinct epitopes on janusin are responsible for repulsion of neuronal cell bodies (Pesheva et al., 1989, Morganti et al., 1990), the initial recognition event between neurons and janusin (Morganti et al., 1990) and growth cone repulsion. Monoclonal tenascin antibodies J1/tn3 and J1/tn5 which bind to the EGF-like repeats and FNIII repeats 4 and 5, respectively, of mouse brain tenascin (Husmann et al., 1992, Figure 28-3), and polyclonal tenascin antibodies neutralize the repulsive properties of tenascin for advancing growth cones (Taylor et al., 1993). In contrast, monoclonal antibody J1/tn2 (Faissner and Kruse, 1990), which recognizes an epitope between FNIII repeats 6 and D (Lochter et

FIG. 28-4. Growth cone behavior at tenascin and janusin boundaries. Phase contrast images of representative retinal ganglion neuron growth cones approaching BSA (A), janusin (B), and tenascin (C) borders marked with colloidal gold-labeled BSA (*upper*) and corresponding velocity plots for these growth cones (*lower*). Numbers in the phase contrast images indicate time (in minutes) since the beginning of the film sequences, made between 24 and 36 hours after plating the retinal explants, and correspond to the times shown in the velocity plots, highlighted by *stars*. *L* denotes the times at which the growth cones first made lamellipodial contact with the border. Note that in Figure A the growth cone advances through the border with no change in velocity or morphology but that in Figures B and C, following contact with the border, the growth cones transiently reduce their rate of advance and turn to grow along the border with no apparent change in morphology. Scale bar in the first panel of Figure A represents 10 μm for all figures. [From Taylor et al. (1993), with permission. JNRS].

al., 1991, Figure 28-3) and monoclonal antibody J1/tn4, which recognizes an epitope within the 3rd and 4th FNIII repeats (Husmann et al., 1992) were ineffective. Antibody J1/tn2 blocks the neurite outgrowth-promoting properties of tenascin for three types of central nervous system neurons (Lochter et al., 1991, Husmann et al., 1992) but does not neutralize the repulsive properties of tenascin for cerebellar neuronal cell bodies (Faissner and Kruse, 1990). This suggests that different epitopes mediate the repulsion of DRG and retinal ganglion neuron growth cones and the repulsion of neuronal cell bodies. Monoclonal antibodies J1/tn4 and J1/tn5 retard cerebellar granule cell migration, in contrast to J1/tn3 (Husmann et al., 1992). Therefore at least two separate domains in the tenascin molecule participate in growth cone repulsion, which are both separate from the domain implied in neurite outgrowth promotion (Lochter et al., 1991). One of these domains, however, appears close to the site involved in cerebellar granule cell migration (Husmann et al., 1992). The location of these various domains is summarized in Figure 28-3.

Over the last few years several publications have highlighted the principle that neurite repulsion or inhibition might be an important mechanism for neurite guidance (e.g., Kapfhammer et al., 1986; Kapfhammer and Raper, 1987; Walter et al., 1987a, 1987b; Caroni and Schwab, 1988a, 1988b; Baier and Bonhoeffer, 1992; see also Patterson, 1988, Walter et al., 1990, Keynes and Cook, 1992, Schwab et al., 1993, for reviews) and janusin and tenascin could also function in this manner when present as boundaries. Janusin is expressed by oligodendrocytes and in central nervous system myelin (Pesheva et al., 1989; Wintergerst et al., 1993; U. Bartsch et al., 1993a), notoriously nonpermissive substrata for neurite outgrowth (Schwab and Caroni, 1988; Fawcett et al., 1989). Tenascin is found in the developing rodent central nervous system (see above) or in areas around stab wounds in the adult central nervous system (McKeon et al., 1991; Laywell et al., 1992; Masuda-Nakagawa et al., 1992). Janusin and tenascin might in addition function as promoters of neurite outgrowth, or at least allow neurite outgrowth, from certain types of neurons when they are expressed uniformly, such as appears to be the case of tenascin in the regenerating mammalian peripheral nervous system and certain regions in the developing central nervous system (see above). The apparently contradictory properties of janusin and tenascin in causing growth cone avoidance in choice assays, and yet promoting growth cone advance in no-choice assays, are reminiscent of a previous study of a repulsive factor present in the chick tectum (Walter et al., 1987a, 1987b). Axons from the chick temporal retina avoid membranes derived from the posterior tectum, an incorrect target tissue for these axons, when given the choice of growing on these membranes or those derived from the anterior tectum, their correct target tissue, but are able to grow as well on posterior as anterior tectal membranes when given no choice. A more recent publication indicates that a gradient of the repulsive factor present in posterior tectal cell membranes of at least 5% per 25 μm is required to prevent growth cone advance (Baier and Bonhoeffer, 1992). It would be of interest to determine whether the same is true for janusin and tenascin, although, to date, shallow gradients of these molecules have not been obvious *in vivo* (in contrast to sharp step gradients at tenascin boundaries). When DRG or retinal ganglion neuron growth cones contact sharp substrate boundaries of janusin and tenascin, the temporary reduction in the rate of growth cone advance is only very rarely, in the case of DRG growth cones, and never, in the case of retinal growth cones accompanied by complete growth cone collapse (Taylor et al., 1993). In the few cases where it was observed, complete growth cone collapse was transient and not reminiscent of the type of growth cone inhibition observed when growth cones contact other nonpermissive substrates, for example, oligodendrocytes (Bandtlow et al., 1990). Several recent studies have suggested that neurite avoidance of inappropriate substrates is mediated by growth cone collapse (Fawcett et al., 1989; Raper and Kapfhammer, 1990; Cox et al., 1990, Davies et al., 1990; Bandtlow et al., 1990; see also Walter et al., 1990; Keynes and Cook, 1992) and that growth cone collapse-inducing molecules can be demonstrated by incorporating them into liposomes and adding them to growth cones growing on permissive substrates (Raper and Kapfhammer, 1990, Cox et al., 1990, Davies et al., 1990). When janusin and tenascin are applied as soluble molecules to either DRG or retinal ganglion neuron growth cones advancing on laminin, no effect on growth cone morphology or rate of advance is seen (Taylor et al., 1993). It appears, therefore, that molecules which guide growth cones by repulsive or inhibitory mechanisms may produce different avoidance reactions in advancing growth cones involving either an interaction with the repellent molecule leading to a change in the direction of growth cone advance, as observed for janusin and tenascin or growth cone collapse, which may finally also result in redirection of neurite outgrowth. Similar mechanisms may be operating to repel DRG neuron growth cones from janusin and tenascin boundaries in choice experiments, and to speed growth cone advance in no-

choice experiments. The DRG neuron growth cone lamellipodia confronting janusin and tenascin borders in choice experiments undergo a localized collapse that can be compared to the collapsed morphology of rapidly advancing growth cones on uniform janusin- or tenascin-containing substrates. Thus, it could be envisaged that the localized lamellipodial collapse seen in DRG neuron growth cones at janusin and tenascin borders in choice experiments is due to a localized change in the concentration of a second messenger, which in turn mediates the localized lamellipodial collapse due to localized cytoskeletal rearrangement. Along these lines, the overall collapsed appearance of DRG neuron growth cones which find themselves surrounded by janusin- and tenascin-containing substrata, in no-choice experiments, could result from a global change in the concentration of the same second messenger and consequent global rearrangement of the growth cone cytoskeleton.

DIVERSE TENASCIN AND JANUSIN FUNCTIONS MAY REQUIRE VARIOUS RECEPTORS

Several receptors have been described which could contribute to mediate tenascin effects, for example integrins (Bourdon and Ruoslahti, 1989; Leahy et al., 1992; Sriramarao et al., 1993; Wehrle-Haller and Chiquet, 1993), the neural chondroitin sulfate proteoglycan CTBP (Hoffman and Edelman, 1987; Hoffman et al., 1988), the heparan sulfate proteoglycan syndecan (Salmivirta et al., 1991), sulfatide (Crossin and Edelman, 1992), and the Ig-superfamily member contactin/F3/F11 (Ranscht and Dours, 1988; Brümmendorf et al., 1989; Gennarini et al., 1989, 1991; Zisch et al., 1992). In addition, interactions of tenascin with other ECM components like fibronectin or collagens might modify the functional properties of the glycoprotein (Chiquet-Ehrismann et al., 1988; Marton et al., 1989; Lightner and Erickson, 1990; Faissner et al., 1990; Probstmeier et al., 1990; Chiquet et al., 1991). Tenascin glycoproteins hence appear as multimodular, multifunctional glycoproteins which exhibit distinct functional sites implied in cell-binding, in antispreading-repulsion events, in cell migration and in the control of neurite growth. In light of these results, tenascin glycoproteins could enclose forming neuronal assemblies, segregate outgrowing fiber tracts or aid in neuron migration during neural development. How the different domains of tenascin interact and which receptors are crucial in these processes remains at present elusive (discussed in Faissner, 1993; Faissner et al., 1994). Also, a proof that tenascin glycoproteins perform diverse functions *in situ* is still missing and will require direct perturbation in adequate *in vivo* systems. A recent experiment was not conclusive in this regard because inactivating the tenascin gene in the mouse does not overtly interfere with mouse development. Whether the fine structure of the nervous system is altered in the TN(−) mutants was, however, not addressed (Saga et al., 1992). Also, analysis has been confined to postnatal stages of development while the investigation of potential long-term effects of the knock-out is still pending. For these reasons, it seems premature to disregard tenascin as "junk protein" with superfluous and spurious expression (Erickson, 1993a).

In search for neuronal ligands mediating the repulsive response to janusin the F3/11 cell surface glycoprotein, a glycosylphosphatidyl-inositol anchored member of the immunoglobulin superfamily, has been identified (Gennarini et al., 1991; Pesheva et al., 1993). F3/11 mediates the initial recognition between a janusin substrate and cerebellar neurons or F3-transfected CHO cell. In cerebellar neurons, the interaction between F3/11 and janusin induces a repulsion consisting of the loss of substrate adhesion with time in culture and inhibition of neurite outgrowth. Antibody blocking experiments show that the avoidance response of neurites at janusin substrate borders is also mediated by F3/11. These results document for the first time a ligand-receptor pair involved in the repulsion of neurons. It is likely that particular mechanisms of signal transduction which are induced by F3/11 lead to the avoidance behavior of growth cones and neuronal cell bodies (Bixby and Harris, 1991). The linkage of an adhesion molecule of the Ig-superfamily to second-messenger systems has already been documented for L1 (Schuch et al., 1989, Atashi et al., 1992). It is interesting that F3/11 is also able to mediate adhesive responses, for example when transfected into CHO-cells (Gennarini et al., 1991), possibly involving another Ig-superfamily molecule, L1 (Kuhn et al., 1991). Consistent with these reports, F11/contactin, the chicken analogue of F3, has recently been shown to interact with restrictin and Ng-CAM, the chicken equivalents of janusin and L1, respectively (Brümmendorf et al., 1993). Future investigations will focus on the fine structure of functional tenascin- and janusin-domains, the identification of complementary receptors and the elucidation of second messenger pathways controlling the cellular responses to these glycoproteins.

The authors thank the German Research Council (DFG) and the Federal Ministry of Research and Technology (BMFT) for

grant support (SFB 317/A7 and FKZ 070 1771/4 to MS and SFB 317/A2 and Fa-159/5-1 to AF) and Mrs. U. Bergmann for the preparation of the manuscript. Andreas Faissner is the recipient of an endowed Hermann- und Lilly-Schilling-Stiftung professorship.

29 Growth factors and their receptors in the peripheral nervous system

MICHAEL SENDTNER

Our understanding of how growth factors and growth factor receptors are involved in the complex mechanisms regulating physiological development and maintenance of the peripheral nervous system has advanced considerably during the past few years. Several major steps in the field have been made: (1) the cloning of brain-derived neurotrophic factor (BDNF) (Leibrock et al., 1989), which led to the identification of the still growing gene family of neurotrophins (Barde, 1990), (2) the identification of the *trk* oncogene as the high-affinity receptor for nerve growth factor (NGF) (Kaplan et al., 1991a, 1991b; Klein et al., 1991a) and the subsequent identification of the *trk* tyrosine kinase gene family of receptor molecules for the neurotrophins (reviewed by Meakin and Shooter, 1992), (3) progress in elucidating how the expression of neurotrophic factors is physiologically regulated in the peripheral nervous system. The analysis of the role of IL-1 in the upregulation of NGF mRNA in peripheral nerves (Heumann et al., 1987b; Lindholm et al., 1987) after lesion was one of the first examples of how cytokines with a defined function in the immune system are involved in the regulation of neuronal regeneration mediated by neurotrophic factors such as NGF. Knowledge about the complex functions of growth factors in the peripheral nervous system is still rapidly increasing, in particular from experiments on transgenic animals with altered expression of these molecules.

This chapter focuses on the specific classes of neurotrophic factors (neurotrophins and ciliary neurotrophic factor), members of pluripotent fibroblast growth factor (FGF) and insulinlike growth factor (IGF) gene families, and the newly identified and molecularly characterized glial growth factors and their functions in the peripheral nervous system.

NEUROTROPHIC FACTORS

Neurotrophins

Neurotrophins are polypeptide molecules that regulate the development and maintenance of specific functions of different populations of nervous cells in the peripheral and central nervous systems (Barde, 1990). This still-growing family of molecules includes at the moment four different molecules:

1. The prototypic nerve growth factor (for details of its discovery see Chapter 30, this volume)
2. Brain-derived neurotrophic factor (Barde et al., 1982, Leibrock et al., 1989)
3. Neurotrophin-3 (NT-3) (Hohn et al., 1990; Maisonpierre et al., 1990; Rosenthal et al., 1990)
4. Neurotrophin-4/5 (NT-4/5) (Berkemeier et al., 1991; Hallböök et al., 1991)

In the case of NT-4, first identified and cloned from *Xenopus* (Hallböök et al., 1991), it was subsequently established that this molecule is the analogue of NT-5 (Ip et al., 1992), which had been cloned from human sources (Berkemeier et al., 1991) at about the same time as NT-4 was identified in *Xenopus*. These four factors share more than 30% sequence homology on the mature protein level, and they are relatively well conserved between mammals. Interestingly, the conserved regions of the four mature neurotrophins include the six cysteines, which are thought to play an essential role in the stabilization of the three-dimensional structure of these molecules. Indeed, when the three-dimensional structure for NGF was solved (McDonald and Hendrickson, 1993), it proved to be a long molecule consisting of three pairs of twisted antiparallel β-strands linked by four loop regions. The cysteine residues form an interlocked, knotlike motif at one end of the molecule, a structural feature since found to be shared by other proteins such as TGF-β2 and PDGF-BB (for review see McDonald et al., 1993). The variable domains between the different members of the gene family reside mainly in the four hairpin loops. They are thought to be responsible for determining the different receptor specificities of the four neurotrophins identified so far.

Specificity of Neurotrophins for Specific Neuronal Populations. *In vitro,* the neurotrophins show differ-

ential effects on populations of neurons whose axons project within peripheral nerves. Nerve growth factor, for example, supports the survival of cultured sympathetic neurons, whereas BDNF (Barde et al., 1982) and NT-4 (Berkemeier et al., 1991) are inactive. Recent evidence suggests that also NT-3 is more specific for *trk*C than for *trk*A or *trk*B (Ip et al., 1993b), thus confirming earlier studies showing that NT-3 might not physiologically support the survival of cultured sympathetic neurons (Hohn et al., 1990) and revising other reports (Glass et al., 1991; Soppet et al., 1991). The neuronal placode-derived sensory neurons of the embryonic day 8 chick nodose ganglion are only supported by BDNF (60% survival), NT-3 (30% survival) (Hohn et al., 1990), and NT-4 (Hallböök et al., 1991), but not by NGF. The actions of BDNF and NT-3 are additive (survival of more than 90% of the originally plated neurons from 8-day-old chick embryos), suggesting that they are mediated by different receptors.

In the case of the neural crest-derived sensory neurons of the dorsal root ganglion, there seem to be subpopulations of neurons that are responsive to either one or more of the neurotrophins. NGF supports about 50% of cultured embryonic day 8 chick dorsal root ganglionic neurons, BDNF supports about 45%, and NT-3 supports about 30% of the cultured neurons (Dechant et al., 1993). If two or all three factors are added to these cultures, additive survival effects are detectable, suggesting that these three neurotrophins act independently through different receptors on different populations of neurons within the embryonic day 8 chick dorsal root ganglia. These results suggest a high degree of specificity of the neurotrophins for responsive neurons, which is consistant with the regulatory roles of these factors on responsive neurons during development and in the adult (Barde, 1989, 1990).

The Receptors for Neurotrophins. Two receptors for NGF have been identified and characterized so far, namely, $p75^{NGFR}$ (reviewed by Meakin and Shooter, 1992) and the protooncogene *trk*A (Kaplan et al., 1991a, Kaplan et al., 1991b, Klein et al., 1991a). In addition, several members of the *trk* tyrosine kinase family have been shown to act as high-affinity receptors for the other neurotrophins, such as *trk*B (Middlemas et al., 1991) as a high-affinity receptor for BDNF (Klein et al., 1991b) and NT-4/5 (Klein et al., 1992), and *trk*C as a high-affinity receptor for NT-3 (Tsoulfas et al., 1993) (Figure 29-1). Original reports (Cordon-Cardo et al., 1991; Klein et al., 1991b; Squinto et al., 1991) have suggested that *trk*A and *trk*B might serve as signal transducing receptors with broader specificity for NGF and NT-3 or BDNF and NT-3, respectively. However, recent data suggest that both in neuronal cells and PC-12 cells, the specificity of *trk*B for BDNF and NT-4/5 seems to be much higher than for NT-3 (Ip et al., 1993b, Tsoulfas et al., 1993). Indeed, recent evidence from cultured embryonic chick nodose neurons has suggested that NT-3, which binds to *trk*B at high concentrations in the culture medium, competes with BDNF as a receptor antagonist rather than an agonist (Dechant et al., 1993). *In vivo*, similar observations have been made that are compatible with the assumption that NGF might act as a competitive antagonist on neurons expressing *trk*B and *trk*C. Survival rates of spinal and facial motoneurons in newborn rats after lesion are decreased rather than increased by NGF addition (Miyata et al., 1986; Sendtner et al., 1992a). Thus the biological responses of neurotrophins seem to be mediated by specific high-affinity receptors which involve the tyrosine kinase cell transmembrane proteins of the *trk* gene family.

It is still not very clear how the p75 neurotrophin receptor molecule contributes to the biological actions of neurotrophins (Meakin and Shooter, 1992). Protein 75, which has been shown to bind NGF, BDNF, and NT-3 with similar low affinity (Rodriguez-Tebar et al., 1990, 1992) does not have a tyrosine kinase domain within its cytoplasmic region. A consensus sequence for the binding of G proteins has been identified (Feinstein and Larhammer, 1990); however, the question is still open whether G proteins contribute to the biological actions of NGF in responsive neurons. Interestingly, the p75 low-affinity neurotrophin receptor is also expressed by glial cells within the peripheral nervous system (reviewed by Johnson et al., 1988). During development, Schwann cell precursor cells express high amounts of p75 protein. At later stages, when Schwann cells cease to divide and become myelinated, p75 expression is downregulated to undetectable levels. However, after lesion, this receptor molecule is again rapidly reexpressed by Schwann cells within the distal stump of the lesioned nerves. The physiological function of the low-affinity neurotrophin receptor on Schwann cells is not clear. Gene targeting (Lee et al., 1992) has shown that mice deficient in this protein are viable, and that they do not show any apparent defects of the sympathetic nervous system. Only sensory deficits are seen, particularly reduced heat sensitivity, which corresponds to decreased density of sensory nerve fibers in the skin of these mice. However, it is not yet clear whether the rate of neuronal loss is increased in the dorsal root ganglia or other neurotrophin-dependent neuronal cell population during the period of naturally

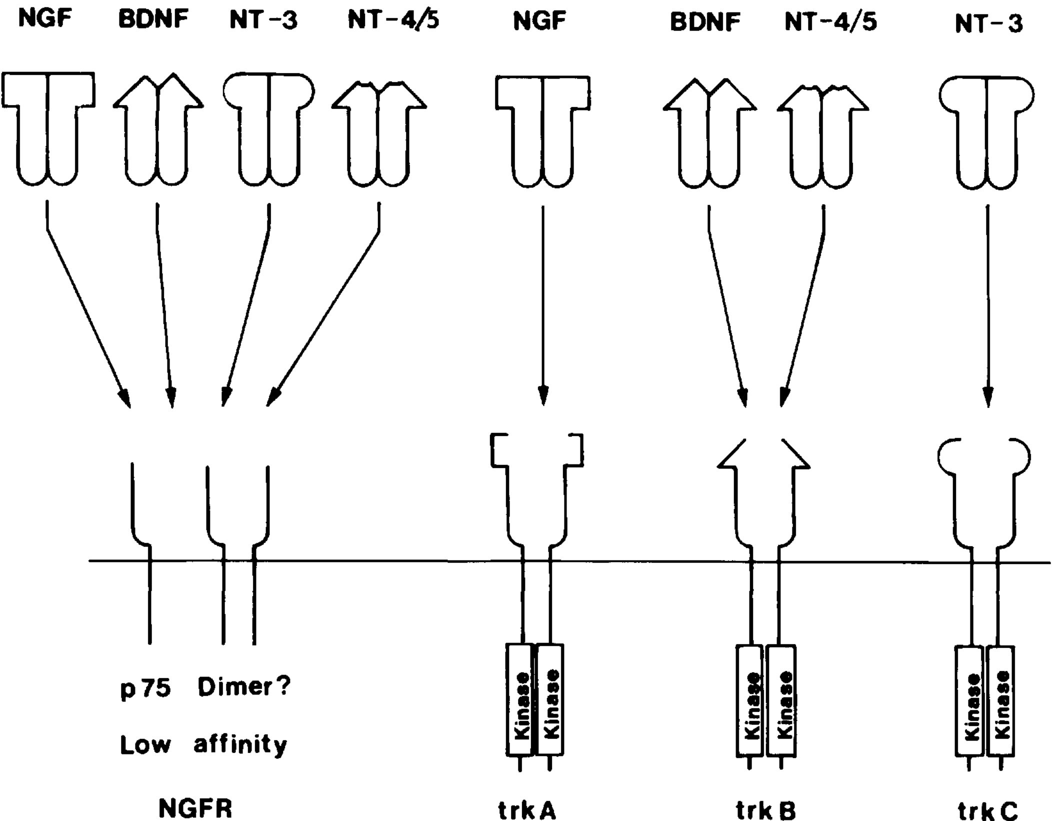

FIG. 29-1. Model of neurotrophin action on target cells. Neurotrophin homodimers activate specific *trk* tyrosin kinases by inducing receptor dimerization. All neurotrophins can bind with similar affinity to the low-affinity nerve growth factor receptor (p75). However, the biological function of this receptor is still unclear.

occurring cell death. The sensory deficits in this mouse could also be due to the lack of expression of p75 on Schwann cells during development, thus leading to indirect impairment of sensory fiber outgrowth to the skin.

In the case of the *trk* gene family of tyrosine kinases, it seems easier to match the temporal and spatial expression of these molecules with functional aspects. The expression of *trk*A on neurons correlates very well with NGF responsiveness (Carroll et al., 1992). Similarly, *trk*B and *trk*C tyrosine kinase expression seems to be restricted to neuronal cells known to be responsive to BDNF and NT-3 (Klein et al., 1989; 1990, Henderson et al., 1993), respectively. This is compatible with the assumption that the actions of neurotrophins on neuronal survival and function are primarily mediated by the *trk* tyrosine kinases.

Function of Target-Derived Neurotrophins in the Peripheral Nervous System. Nerve growth factor is the prototype of a target-derived neurotrophic molecule. Only low amounts of NGF mRNA are found in target tissues of responsive neurons, which, within the peripheral nervous system, are usually nonneuronal cells. These low amounts of NGF mRNA and protein in target tissues correspond to the low quantities of NGF protein detectable by highly sensitive immunoassays (reviewed by Barde, 1989). For example, in the adult rat iris, which is densely innervated by NGF-dependent sympathetic nerve fibers, about 1.9 ng of NGF per gram of tissue wet weight are found (Heumann et al., 1987a). During embryonic development, the low quantities of NGF protein do not seem to be sufficient to saturate the high-affinity binding sites of all dependent neurons, so that about half of them degenerate because of the limited availability of this factor (reviewed by Barde, 1989). NGF binds to dependent neurons via high-affinity receptors (K_d in the range of 10^{-11}M), which are taken up in membrane-bound vesicles. These vesicles, which still contain intact NGF protein, are retrogradely transported from the nerve terminal to the cell body. Signal transduction is initiated after NGF is bound to its high-affinity receptors (Meakin and Shooter, 1992). However, it is still unresolved whether signaling events are generated at the nerve terminals after binding of NGF to its receptor, or at later stages when the NGF-containing vesicles have been transported to the corresponding nerve cell

bodies. Many pieces of evidence have shown that NGF is important for the survival of neurons during a critical period of development when about half of the postmitotic neurons of the NGF-dependent sympathetic and neuronal crest-derived sensory neurons are eliminated (Barde, 1989, Oppenheim, 1985, Johnson et al., 1986). Furthermore, NGF from target tissues regulates functionally important features of the neurons during postnatal life, such as transmitter synthesis. In sympathetic neurons, levels of tyrosine hydroxylase are elevated after exogenous NGF addition, and the enzyme levels are downregulated after addition of neutralizing antibodies against this factor (reviewed by Thoenen and Barde, 1980). Similarly, in sensory neurons, substance P levels are dramatically reduced after addition of neutralizing antibodies against NGF (Otten et al., 1980), suggesting that NGF plays a key role in the regulation of transmitter synthesis by target tissues. Although methods for measurement of BDNF, NT-3, and NT-4 protein levels in peripheral tissues are not yet established, the levels of the corresponding mRNAs coding for these factors are in general consistent with a similar function of these factors for their responsive or dependent neurons, as established for NGF. For example, BDNF and NT-3 mRNAs are found in small but significant levels in gut, lung, and heart of adult mouse, tissues known to be strongly innervated by sensory neurons of the nodose ganglion (Hofer et al., 1990; Hohn et al., 1990; Maisonpierre et al., 1990). In addition, BDNF and NT-3 mRNAs are also expressed in skeletal muscle, the target of BDNF and NT-3 responsive motoneurons and proprioreceptive sensory neurons (Hohn et al., 1990; Maisonpierre et al., 1990; Koliatsos et al., 1993). The distribution of NT-4 mRNA expression in peripheral tissues is yet to be studied in detail. Preliminary studies have shown that very low amount of NT-4/5 mRNA are detectable in skeletal muscle (Berkemeier et al., 1991; Ip et al., 1992) and skin (Henderson et al., 1993, Ibanez et al., 1993), the targets of NT-4/5 responsive motor and sensory neurons. Relatively high levels of NT-4/5 mRNA are also found in ovary and thymus. However, the physiological role of NT-4/5 in these tissues remains to be established.

Expression of Neurotrophins by Neurons Within the Peripheral Nervous System: Potential Physiological Function. Recently it has been found that members of the neurotrophin gene family are also expressed by developing sensory and motor neurons. By *in situ* hybridization techniques, BDNF mRNA has been detected in developing dorsal root ganglionic sensory neurons from embryonic day 13 to adulthood (Ernfors and Persson, 1991). In addition, relatively high levels of NT-3 mRNA have been detected in spinal motoneurons of the rat between embryonic day 13 and birth. These results were unexpected, as both the sensory neurons and the spinal motoneurons have been shown to be responsive to these molecules. Indeed, on the basis of these results, the question has been raised whether these neuronally derived trophic factors could act locally in an autocrine or paracrine fashion. This is conceivable, as a significant population of the sensory neurons within the developing dorsal root ganglia are responsive to BDNF, both *in vitro* and *in vivo* (Hofer and Barde, 1988; Barde, 1990; Oppenheim et al., 1992b). Indeed, cultured sensory neurons from embryonic day 4.5 chick embryos, which are not yet dependent on neurotrophins for their survival but produce BDNF themselves, seem to depend on the endogenous BDNF for their maturation, as shown with BDNF antisense oligonucleotides in cell culture (Wright et al., 1992). These results argue in favor of the existence of autocrine actions of neurotrophins. However, it is still open as to whether such autocrine effects play a role during the period of physiologically occurring cell death.

As an alternative possibility, it has been suggested that the NT-3 produced in motoneurons would serve as a trophic factor for the proprioceptive sensory neurons innervating the ventral horn (Ernfors and Persson, 1991). This possibility is supported by the observation that transsection of the central processes of dorsal root sensory neurons in newborn rats results in significant rates of cell death in the affected dorsal root ganglia (Johnson et al., 1986), suggesting that the interruption of the central connection of sensory neurons leads to loss of trophic support from the central nervous system. However, it is not possible at the moment to draw final conclusions on the physiological consequences of the expression of NT-3 in motoneurons.

The Regulation of Nerve Growth Factor and Brain-Derived Neurotrophic Factor mRNA in Peripheral Nerves After Lesion. In nonneuronal cells of the adult peripheral nerve, neither NGF nor BDNF are expressed under physiological conditions (Heumann et al., 1987b, Meyer et al., 1992). However, after lesion of peripheral nerves, NGF mRNA is rapidly upregulated at the lesion site and in the distal stump (Figure 29-2). The increase of NGF mRNA in these two regions is biphasic: After an initial rapid increase during the first hours after lesion, NGF mRNA levels decrease again before a second, longer lasting, increase of NGF mRNA occurs. This second phase of NGF induction is due to interleukin-1 (IL-1) released

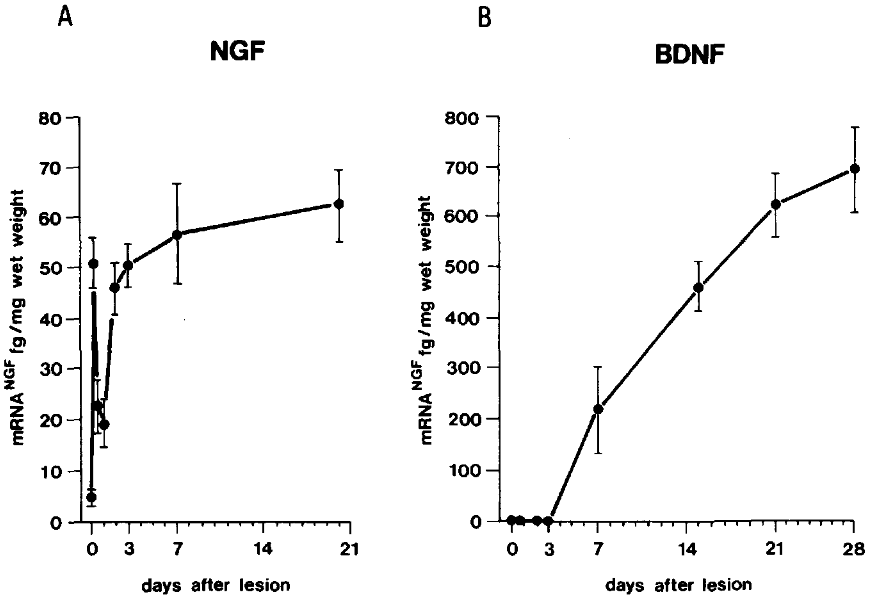

FIG. 29-2. Comparison of the time course of mRNA induction for nerve growth factor (*NGF*) and brain-derived neurotrophic factor (*BDNF*) mRNA in the distal segment of the sciatic nerve during the first weeks after lesion. [From Meyer et al. (1992), with permission.]

by macrophages invading the lesioned nerve (Heumann et al., 1987b; Lindholm et al., 1987). Interestingly, the increase of NGF mRNA is not restricted to nerves that contain the nerve fibers of NGF-dependent sensory or sympathetic neurons. For example, it occurs also in the lesioned facial nerve, which contains only the axons of NGF-independent motoneurons (Heumann et al., 1987a).

NGF is not the only neurotrophin that is upregulated after nerve lesion. BDNF mRNA is also increased up to high levels at the lesion site and the distal part of the lesioned nerve (Meyer et al., 1992). However, the increase of BDNF mRNA is much slower than that of NGF mRNA. It was not detectable before the second half of the first week after lesion, and increased continuously during the first 4 weeks after lesion. One month after lesion, BDNF mRNA levels were 10 times higher than the levels of NGF mRNA, and a plateau was not reached up to that time (Figure 29-2). The massive and long-lasting increase of BDNF mRNA in rat peripheral nerves after lesion might be of considerable significance to BDNF-dependent sensory and motor neurons during regeneration.

Ciliary Neurotrophic Factor

Ciliary neurotrophic factor (CNTF) has originally been identified as an activity present in eye extracts, which supports the survival of embryonic chick ciliary neurons in culture (Helfand et al., 1976). Subsequent studies with semipurified CNTF showed that this neurotrophic factor differed significantly from the neurotrophins by its broad spectrum of responsive neurons of the embryonic chick. CNTF not only supports ciliary neurons, but also sympathetic, sensory (Barbin et al., 1984), nodose, trigeminal, and, in particular, motoneurons (reviewed in Sendtner et al., 1991). Moreover, CNTF has also been shown to act on glial precursor cells of the oligodendrocyte lineage (Lillien and Raff, 1990) and to support the survival of differentiated oligodendrocytes in culture (Louis et al., 1993). The final purification and subsequent cloning of the cDNA (Lin et al., 1989; Stöckli et al., 1989) of CNTF showed that this factor is not structurally related to the neurotrophins. In particular, CNTF lacks a hydrophobic leader sequence, which is typical of secretory proteins such as the neurotrophins. It is not yet known how CNTF is made available by cells where it is produced in order to act on its responsive neurons.

Regulation of Ciliary Neurotrophic Factor Expression. In addition to these specific properties, the temporal and spatial expression of CNTF mRNA and protein differs distinctly from that of the neurotrophins. In the developing rat, CNTF expression is absent during the time periods when neurons differentiate or when a significant proportion of postmitotic peripheral neurons undergo cell death (Stöckli et al., 1991). Therefore it was assumed that CNTF does not play an essential function during

these developmental stages. In the rat, the first expression of CNTF is detectable in Schwann cells of the peripheral nerves at postnatal day 4, the time when Schwann cells stop dividing and myelination starts (Stöckli et al., 1989). In the adult peripheral nervous system, the very high amounts of CNTF in peripheral nerves are localized in the cytoplasm of myelinating Schwann cells (Stöckli et al., 1991; Rende et al., 1992). It is still not clear whether CNTF can be released from unlesioned Schwann cells or whether release, and thus availability, for responsive neurons occurs only after nerve lesion. After peripheral nerve lesion in the adult rat, CNTF mRNA is rapidly downregulated in the distal stump. However, CNTF protein, biological activity, and immunoreactivity are still detectable (Friedman et al., 1992; Sendtner et al., 1992b). One week after lesion, CNTF protein levels are still 1000 times higher than the levels of NGF (Table 29-1), whose expression is upregulated after lesion. Thus it seems plausible that CNTF might play a role in maintaining survival of lesioned motor and sensory neurons, at least during the early stages after peripheral nerve lesion.

The Ciliary Neurotrophic Factor Receptor Complex. A specific low-affinity receptor component for CNTF has been identified and cloned (Davis et al., 1991). This molecule, which lacks an intracellular and a transmembrane region, is anchored to the membrane via glycosylphophatidylinositol (GPI) anchor. Recently, evidence has been presented that two further transmembrane molecules are necessary for CNTF signal transduction: the signal transducing subunit of the IL-6 receptor complex, gp130 and the LIFRβ (reviewed by Taga and Kishimoto, 1992, Ip and Yancopoulos, 1992). The low-affinity CNTFRα also exists in a soluble form, which has been detected in cerebrospinal fluid and in serum of adult humans (Davis et al., 1993). This indicates that CNTF-responsive cells do not necessarily depend on endogenous CNTFRα expression (Figure 29-3). In the presence of soluble CNTFRα, the expression of gp130 and LIFRβ is sufficient to render cells responsive to CNTF. If this also occurs under physiological conditions *in vivo,* then the spectrum of CNTF responsive cells would go far beyond the neuronal cells which have been shown to express CNTFRα (Ip et al., 1993a).

The Fibroblast Growth Factor Gene Family

Fibroblast growth factors are a large family of growth factors with actions on a great variety of cells (for review see Klagsbrun, 1989; Goldfarb, 1990). Similar to CNTF, the prototypic FGFs—acidic FGF (FGF1) and basic FGF (FGF2)—lack a signal peptide sequence. Thus it is not known how these molecules are released from synthesizing cells in order to exert their physiological function. In contrast, the other six known members of the FGF gene family are secreted from synthesizing cells.

Binding of Fibroblast Growth Factors to Heparan Sulfate Proteoglycans. In contrast to the known neurotrophins and to CNTF, the members of the FGF gene family show affinity (in the range of 10^{-7} to 10^{-9} mol) to the glycosaminoglycan heparin (Yayon et al., 1991; for review see Givol and Yayon, 1992; Partanen et al., 1992). This has led to the identification of extracellular matrix and cell surface-bound heparan sulfate proteoglycans (HSPG) as a class of physiological binding sites for these molecules. HSPGs are ubiquitous macromolecules with a high degree of structural variability, whose composition is strongly regulated both during development and in a tissue specific manner (for review see Bernfield

TABLE 29-1. *Comparison of the Levels of NGF, CNTF, and FGF1 Biological Activity in the Sciatic Nerve of the Adult Rat After Lesion*

	NGF (trophic units/mg protein)	CNTF (trophic units/mg protein)	FGF1 (mitotic units/mg protein)
Unlesioned sciatic nerve	0.6 ± 0.2[a]	17500 ± 2500[b]	768 ± 67[c]
Distal sciatic nerve 7 days after lesion	2.5 ± 0.6[a]	3150 ± 620[b]	9 ± 4[c]

Data are modified according to Heumann et al. (1987), Sendtner et al. (1992a), and Eckenstein et al. (1991).

NGF, nerve growth factor; CNTF, ciliary neurotrophic factor; FGF1, fibroblast growth factor-1.

[a]One trophic unit of NGF corresponds to about 75 pg/ml, which is the amount necessary for stimulating half-maximal survival of embryonic day 8 chick dorsal root sensory neurons in culture.

[b]One trophic unit of CNTF corresponds to about 30 pg/ml, the amount that supports half maximal survival of embryonic day 8 chick ciliary neurons in culture.

[c]One mitotic unit of FGF1 corresponds to about 150 pg/ml which induces half-maximal stimulation of mitosis in cultures of AK12-2B cells.

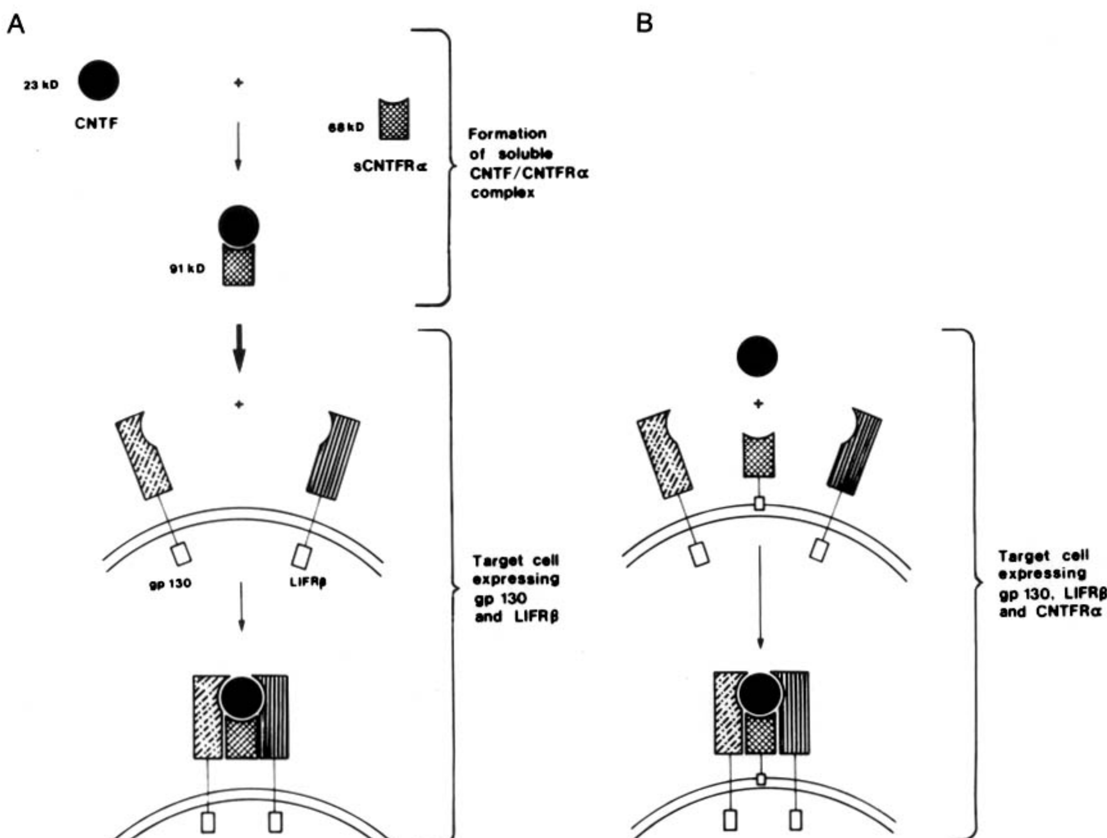

FIG. 29-3. Model of ciliary neurotrophic factor association with its receptor components. (A) After association with the soluble CNTFRα in body fluids (blood, cerebrospinal fluid) CNTF can act on any cell expressing gp 130 and LIFRβ. (B) In neuronal cells, all three components of the CNTF receptor are expressed so that the association with a soluble CNTFRα is not necessary for CNTF action.

et al., 1992). Recently it has been shown that the specificity of the major embryonic forms of HSPG in developing neuroepithelium changes during development from a form with relative specificity for FGF1 to another form that preferentially recognizes and potentiates the mitotic actions of FGF2 (Nurcombe et al., 1993). The specificity of HSPG for different members of the FGF gene family and the resulting implications for the physiological functions of the FGFs are still poorly understood. The basal membranes of peripheral nerves and target tissues, such as skeletal muscle, bind different members of the FGF gene family (Vaca et al., 1989; Hughes et al., 1993; for review see Klagsbrun, 1989; Goldfarb, 1990). It is an intriguing possibility that the composition of these basal membranes can modify the actions of different members of the FGF gene family on responsive neurons and nonneuronal cells within the peripheral nervous system.

Similarly, nothing is known so far about the molecular nature of HSPG on the cell surface of glial cells and neurons. Analysis of the conditions required for high-affinity binding of FGF2 to FGF receptors has revealed the importance of the HSPG, which, together with FGF2 as a complex, binds and activates FGF receptors (Yayon et al., 1991). Thus, the responsiveness of different cells to the FGFs could not only be dependent on the expression of specific FGF receptors, but also on the availability of the specific HSPGs. A variety of different FGF receptors has been cloned so far from avian and mammalan sources, and some types of FGF receptor mRNAs have in the meantime also been identified in central and peripheral neurons (Wanaka et al., 1990; see also reviews of Partanen et al., 1992; Givol and Yayon, 1992).

Functions and Expression of Fibroblast Growth Factors in the Peripheral Nervous System. In spite of many studies on the function of FGF1 and FGF2 on cultured neuronal and nonneuronal cells, not much is known on the physiological function of the FGFs in the peripheral nervous system. FGF1 and FGF2 have so far been identified as survival factors for cultured ciliary and motoneurons (Unsicker et al., 1987, 1992a, 1992b; Arakawa et al., 1990). Recently also

FGF3 (K-FGF) and FGF5 were shown to be active on motoneuron survival (Hughes et al., 1993). At least for FGF2, survival of ciliary and motoneurons has been shown to be supported in single-cell cultures (Sendtner et al., 1991; Unsicker et al., 1992a), demonstrating that the effect of FGF2 on these neurons is direct and not mediated by other cells in the peripheral nervous system. Moreover, FGF1 and FGF2 can induce mitosis of cultured Schwann cells (Davis and Stroobant, 1990), which suggests a further role of the members of this gene family in the peripheral nervous system.

FGF1 is expressed in very high quantities in neurons, particularly in motoneurons, and FGF1 protein is detectable in axons of peripheral nerves (Eckenstein et al., 1991). After lesion, FGF1 protein and biological activity levels are rapidly decreased in extracts from the distal parts of the lesioned nerves (see Table 29-1). This does not fit with a role as a lesion factor for the injured neurons, as has been suggested for CNTF.

It has been suggested that FGF2 is expressed in skeletal muscle and might act as a target derived neurotrophic factor for spinal motoneurons (Vaca et al., 1989). However, the only evidence presented was the molecular size of semipurified activity (about 18 kD) and the affinity to heparin, two parameters that are shared by FGF-5. In contrast to FGF-2, significant levels of FGF-5 mRNA are found in developing and adult skeletal muscle both by *in situ* hybridization techniques and Northern blot analysis (Haub and Goldfarb, 1991; Hughes et al., 1993). In addition, immunoprecipitation studies have shown that FGF-5 is the major motoneuron survival activity from embryonic rat skeletal muscle extracts for cultured chick motoneurons. In summary, future studies have to show how the FGFs are involved in the complex interactions between target tissues, Schwann cells, and neurons within the peripheral nervous system.

Insulin-like Growth Factors

IGF-I and IGF-II are synthesized by a variety of tissues, including the liver, pituitary, and nervous system, and are present in relatively high concentrations in serum and cerebral fluid (Recio-Pinto et al., 1986). During the last few years, evidence has increased, suggesting that these factors could play a physiological role in the neuromuscular system: They have been shown to promote neurite outgrowth from sympathetic and sensory neurons, and IGF-I is retrogradely transported in the sciatic nerve of the adult rat (Hansson et al., 1987). Furthermore, embryonic chick (Arakawa et al., 1990) and rat motoneurons in culture can survive and grow neurites in the presence of IGF-I and IGF-II, and these cells express high-affinity binding sites for these molecules on their cellular processes (Caroni and Grandes, 1990). The injection of IGF-II on the surface of the gluteus muscle of the adult rat induces nodal sprouting of innervating nerve fibers and terminal sprouting at the endplates (Caroni and Becker, 1992). During development both IGF-I and IGF-II mRNA expression in muscle are sharply decreased at the onset of the developmental period of synapse elimination, and the mRNAs for both factors are reexpressed in skeletal muscle after denervation.

GAP-43 and tubulin-α_1 expression in motoneurons, which are also both decreased during synapse elimination, can be maintained at significant levels by the local addition of exogenous IGF-I during the period of synapse elimination. The increase of IGF-I mRNA after muscle denervation in adult animals appears to occur more rapidly than that of IGF-II, and both muscle fibers and interstitial cells might be the source of these factors 1 week after muscular denervation. In addition to the increased IGF expression in muscle, IGF-I receptor mRNA expression is induced in the corresponding spinal motoneurons. It can be concluded from these results that elevated levels of IGFs in denervated muscle, and probably also in distal parts of lesioned nerves, might trigger coordinate regenerative reactions, which lead to nerve sprouting under pathophysiological conditions.

Cooperative Actions of Target- and Glial-Derived Neurotrophic Factors on Spinal Motoneurons

The skeletal musculature is innervated by motoneurons whose cell bodies reside in either the ventral spinal cord or in brainstem motor nuclei. The peripheral nerves consist to a considerable part of motoneuron axons, and the loss of motor function appears as the predominant impairment after damage of peripheral nerves. Thus the identification of the growth factors that support survival and regeneration of adult motoneurons is of particular clinical relevance.

The establishment of highly enriched cell cultures of embryonic chick spinal motoneurons has helped to identify a variety of neurotrophic molecules and growth factors, which can keep these cells alive in culture. Such factors include CNTF, FGF2, FGF5, and, to a lesser extent, FGF1, FGF3, and IGF-I (Arakawa et al., 1990; Hughes et al., 1993). Leukemia inhibitory factor (LIF), which is structurally related to CNTF (Bazan, 1991) and shares at least two re-

ceptor subunits (gp 130 and LIFRβ) with CNTF (Ip and Yancopoulos, 1992), has been identified as a survival factor in rat motoneuron cultures (Martinou et al., 1992). At least some of these factors are also active in supporting motoneuron survival *in vivo,* both during embryonic development (Oppenheim et al., 1991, 1992b; Nurcombe et al., 1991), and after peripheral nerve lesion in newborn rats (Sendtner et al., 1990, 1992a; Yan et al., 1992; Koliatsos et al., 1993). In particular, CNTF, BDNF, and NT-3 have been shown to be active. Interestingly, FGF2 did not show significant survival effects on motoneurons under the same experimental conditions where CNTF and BDNF were active (Nurcombe et al., 1991; Oppenheim et al., 1992a).

The positive effects of BDNF, NT-3, and NT-4/5 on motoneuron survival seem to be direct effects, as isolated and highly enriched embryonic rat motoneurons in culture can survive in the presence of either BDNF, NT-3, or NT-4/5 (Henderson et al., 1993). It has also been shown that these cells express both *trk* B and *trk* C in cell culture and *in vivo* (Henderson et al., 1993), which suggests that the survival effects are mediated via these specific receptor molecules. These data show that molecules of the neurotrophin gene family are also capable of supporting motoneuron survival *in vivo* in a similar manner to ciliary neurotrophic factor.

In contrast to CNTF, however, both NT-3 and BDNF are expressed during embryonic development in specific regions both of the central and peripheral nervous system and in the periphery. Both in the developing and in the adult rat, significant quantities of BDNF mRNA have been detected in the target tissues of spinal motoneurons, namely, skeletal muscle. In comparison to BDNF, the effect of NT-3 seems quite small, and it is not clear whether NT-3 supports only a small subpopulation of motoneurons. Neurotrophin-3 mRNA has been reported to be expressed at high levels in the rat spinal cord between embryonic days 13 and 16 (Ernfors and Persson, 1991). Thereafter, expression decreases gradually to barely detectable levels at birth. Using *in situ* hybridization techniques, the spinal motoneurons themselves have been identified as the site of synthesis of NT-3. It is not clear at the moment whether endogenous production of NT-3 in motoneurons could act in an autocrine manner during development, or whether only postnatally do the relatively high quantities of NT-3 produced in muscle contribute to the target-derived neurotrophic input to motoneurons during later development. Further studies, such as gene-targeting experiments, have to be carried out in order to judge the functional relevance of NT-3 for developing postnatal motoneurons.

The recent observation that BDNF expression is upregulated in the sciatic nerve of the adult rat after lesion (Meyer et al., 1992), is particularly interesting when these results are compared to those of CNTF. CNTF, which we have found to be highly active in supporting survival of lesioned facial motoneurons (Sendtner et al., 1990), is expressed in high amounts in myelinated Schwann cells of peripheral nerves of the adult rat. After lesion, significant quantities of CNTF protein seem to persist for at least 1 week in the lesioned nerve. Immunohistochemistry at the lesion site and the distal nerve segment has shown that CNTF is present in the extracellular space and it seems to be available to regenerating axons (Figure 29-4). The expression of BDNF starts with a delay of at least 3 days after lesion of the sciatic nerve (Figure 29-2), and there is a gradual increase up to the third and fourth week after lesion. Thus, after nerve lesion, motoneurons are supported first by CNTF released from injured Schwann cells, and then by BDNF at later postinjury stages, and BDNF would then support the regeneration of motoneurons to the periphery. The observation that BDNF and CNTF can significantly support the survival of motoneurons after lesion in postnatal animals indicate that these factors could have important functions on motoneurons, and also mediate the regeneration to the periphery after neuronal lesion.

NEURON-DERIVED GROWTH FACTORS FOR PERIPHERAL GLIAL CELLS

In vertebrates, not only do nonneuronal cells provide growth or trophic factors for survival and functional maintenance of neurons, but also regulatory interactions between neurons and nonneuronal cells have been identified. For example, the capability of amphibians to regenerate limbs after amputation is nerve-dependent, and it is believed that soluble factors from neurons play an essential role in this process. Also, in higher vertebrates where such dramatic regenerative events do not occur, nerve cells seem to play a major regulatory role both for developing and the adult Schwann cells. Schwann cell precursor cells from embryonic rat sciatic nerves cannot survive in culture without soluble proteins, which are provided from neurons. Although the responsible molecules are not identified so far, it has been shown that members of the FGF gene family are active in supporting the survival of cultured Schwann cell precursors (Jessen and Mirsky, 1992).

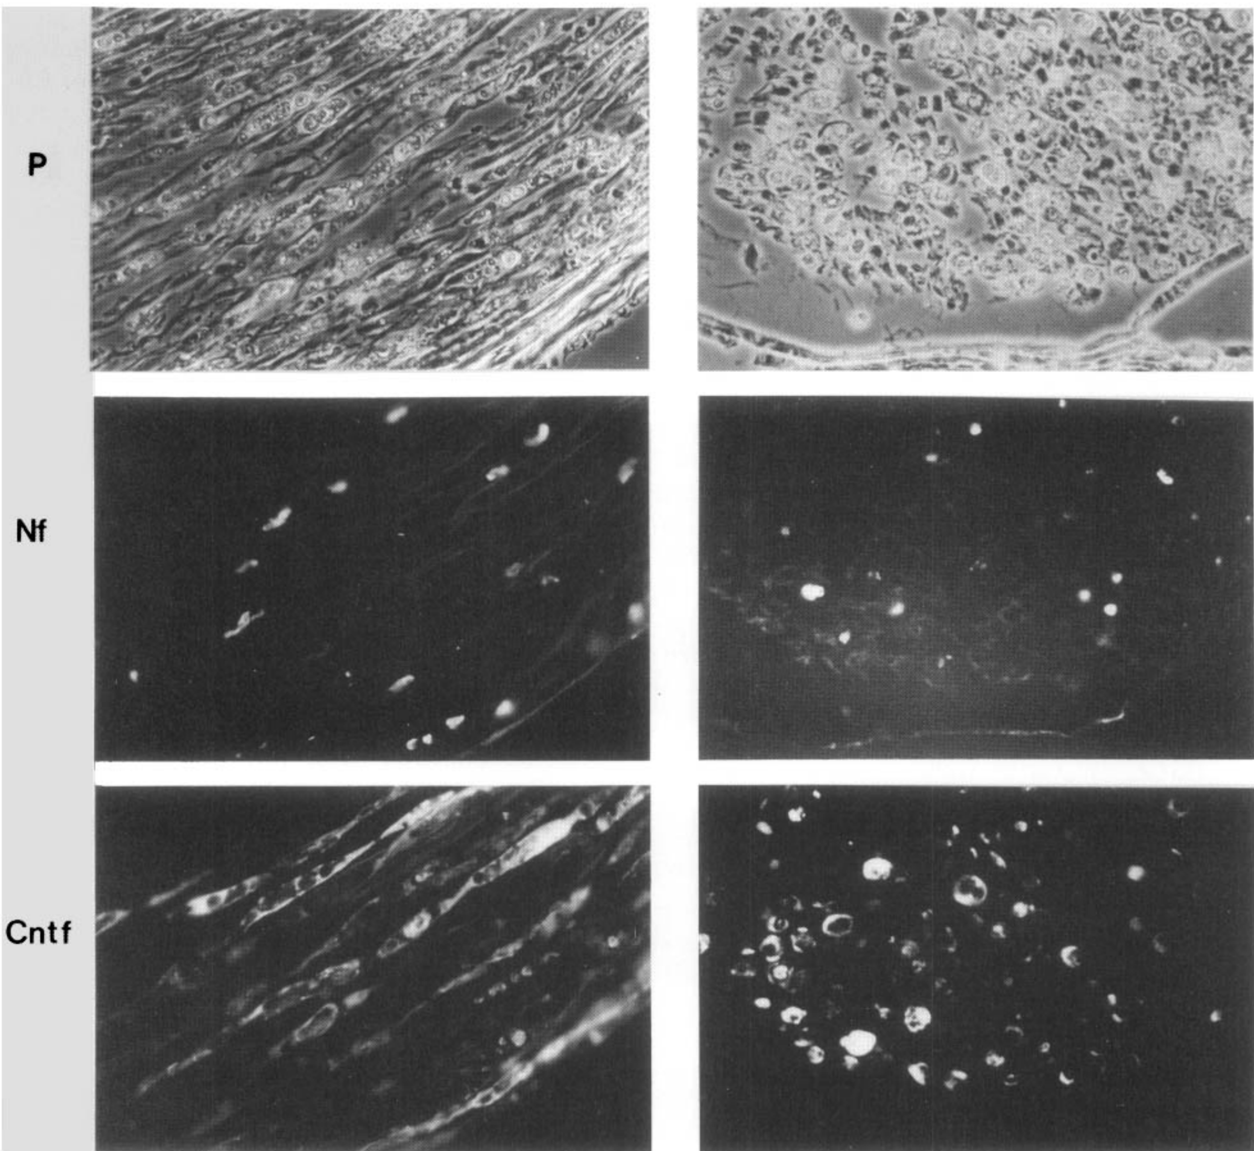

FIG. 29-4. Immunolocation of ciliary neurotrophic factor in sections of the sciatic nerve 6 days after transsection. (*Left*) Longitudinal section. (*Right*) Transverse section. Neurofilament and CNTF immunoreactivity were detected in the same sections by double-labeling techniques as described in Sendtner et al. (1992b). P, phase contrast; Nf, neurofilament immunohistochemistry; Cntf, ciliary neurotrophic factor immunohistochemistry. Six days after sciatic nerve transsection in the adult rat when most of the axons are degraded, CNTF immunoreactivity is still detectable in association with myelin breakdown products, basal membranes, and at extracellular locations where neurofilament staining indicates axonal remnants.

Glial Growth Factor

Postnatally, differentiated Schwann cells usually do not divide in peripheral nerves of higher vertebrates. However, after nerve injury, they dedifferentiate and proliferate rapidly. It has been proposed for a long time that neuron-derived mitogens are involved in this process. Evidence was presented as early as 1978 (Raff et al.) that bovine brain and pituitary extracts contain soluble factors that stimulate the mitosis of Schwann cells in culture. It has been deduced from these experiments that neuronal cells might be capable of synthesizing such factors and thus are able to exert control over cell division and differentiation of these glial cells during development. However, only recently has the molecular nature of these factors from bovine brain and pituitary gland been identified (Marchionni et al., 1993). The glial growth factors are identical with the recently

identified ligands (Wen et al., 1992) for the p185 *erb* B2 tyrosine kinase (also known under the name *neu* oncogene). A transformed version of this protooncogenic tyrosine kinase receptor, has originally been identified as a dominant transforming gene in neurogliomas and schwannomas after experimental tumor induction with ethylnitrosourea in rats (Kokai et al., 1987; also summarized in Wen et al., 1992).

The following pieces of evidence have now been presented which argue for a physiological involvement of glial growth factors and the corresponding p185 *erb* B2 tyrosine kinase receptor in the interactions between neurons and glia:

1. Recombinant glial growth factors can stimulate the mitosis of isolated Schwann cells in culture. There are both membrane bound forms of the active factors, which are encoded by splice variants with a cytoplasmic and transmembrane domain, and soluble splice variants that lack cytoplasmic and transmembrane domain.
2. The receptor for these ligands, the p185 *erb*B2 tyrosine kinase molecule, is physiologically expressed by Schwann cells during development, and is upregulated during Wallerian degeneration (Cohen et al., 1992). Furthermore, this molecule is autophosphorylated upon exposure of cultured Schwann cells to different splice variants of glial growth factor, indicating that p185 *erb*B2 indeed could transduce the signal upon binding of its corresponding ligands.
3. Glial growth factors are expressed by motoneurons in the developing spinal cord and by sensory neurons of the dorsal root ganglia of the mouse at the time when the axons of these neurons grow out within the prospective peripheral nerves, which coincides with the beginning of the period when the mitosis rates of Schwann cells in peripheral nerves are highly increased (reviewed by Jessen and Mirsky, 1992).

However, the expression of glial growth factor expression is maintained for a prolonged period. It seems likely that these molecules also trigger other features of Schwann cell differentiation, such as ensheathement of axons and myelination. Indeed, the function of these molecules are not restricted to the interactions between neuronal and glial cells. At the same time when the ligands for *erb*B2 were identified to act on Schwann cells, the same molecules were found to exert another important function within the peripheral nervous system, that is, the potentiation of acetylcholine receptor expression in skeletal muscle. The activity in chick brain described first in the late 1970s, which induces acetylcholine receptor expression in cultures of myotubes or muscle cells, is identical to glial growth factor (Corfas et al., 1993; Falls et al., 1993).

The analysis of the biological function of the *erb*B2 ligands has just begun, and it appears that the results described here represent only the beginning of the understanding of how neuronal cells regulate properties of Schwann cells and their target cells in the peripheral nervous system on the molecular level.

CONCLUSION

In summary, a variety of different neurotrophic and growth-promoting factors have been identified at the molecular level, which contribute to the regulation of cell-cell interaction in the peripheral nervous system. Most of these factors were identified by their effects on cultured cells *in vitro*, and it is a focus of present research to analyze the physiological function of each factor *in vivo*. Evidence is increasing that different molecules might act together to promote complex functions such as the regeneration of lesioned nerve fibers. New techniques such as gene targeting by homologous recombination, or the establishment of transgenic animals that overexpress the genes of such factors, under the direction of tissue-specific promoters, might help in the future to elucidate the roles of these molecules in the functional maintenance of the peripheral nervous system.

I would like to thank Hans Thoenen and R. A. Hughes for helpful comments and critical reading of the manuscript, and M. Meyer for permission to reproduce Figure 29-2.

30 Growth factors and their receptors in the central nervous system

G. LABOURDETTE AND M. SENSENBRENNER

GROWTH FACTORS AND THEIR RECEPTORS

Nerve Growth Factor and Epidermal Growth Factor

The first growth factor to be characterized was discovered by Levi-Montalcini and coworkers. In their *in vitro* investigations these authors showed that a soluble extract of mouse sarcoma cells stimulated fiber outgrowth from explanted sympathetic and dorsal root ganglia. The soluble factor responsible for this effect was called *nerve growth factor* (NGF) and was subsequently found in high concentration in adult male mouse submaxillary gland (review by Levi-Montalcini, 1987). Later, a second growth factor, the *epidermal growth factor* (EGF) was detected also in the mouse submaxillary gland, on the basis of its stimulatory effect on the development of the epidermis of mouse embryos *in vivo*. Many other growth factors have been characterized since then and most of them have been shown to occur in brain.

Classification and Mode of Action of the Growth Factors

Growth factors are polypeptides synthesized by most tissues that contribute to the control of cell developmental processes like proliferation, differentiation, survival, migration, and maturation and that act usually by binding to membrane receptors. In most cases they elicit various (pleiotropic) effects in a wide variety of cells. A classification of the growth factors related to glia is proposed in Table 30-1 and Table 30-2. The ubiquitous growth factors act on and are found in many cells, and are actually families of factors. They are shown in Table 30-1, with the number of amino acids found in the more mature forms and the names of their receptors when they are known. Other growth factors related to glia have been classified in Table 30-2.

In the brain, before the occurrence of the blood-brain barrier (a few days after birth in rat) growth factors from the bloodstream can act on nerve cells. Afterward, the growth factors are produced endogenously.

The various classes of structure of the growth factor receptors are schematically shown in Figure 30-1. Most growth factor receptors are monomeric and have a tyrosine kinase activity in their intracellular domain, such as fibroblast growth factor receptors (FGFRs) (Fantl et al., 1993). Receptors of insulin-like growth factor-1 (IGF-1) and insulin have a heterotetrameric structure. Transforming growth factor β (TGFβ) receptors I and II have a serine-threonine activity in their cytoplasmic domain. Some other receptors do not have an enzymatic activity; they can elicit their effects through an interaction with G proteins, such as tumor necrosis factor-αR (TNFαR) or thrombin-R, or through the formation of complexes with other receptors, such as interleukin-6Rα (IL-6Rα), which has a very small cytoplasmic domain, or ciliary neurotrophic factor-Rα (CNTFRα), which is anchored to the plasma membrane via a glycosylphosphatidylinositol linkage. It seems that, in order to be activated, most, if not all, growth factor receptors must form complexes before or after the binding of the ligands (Figure 30-2). Glycosaminoglycans have been reported to be necessary for FGFRs and possibly for TGFβRs activation, probably by presenting the ligands to the enzymatic receptors. Some high-affinity receptors are formed by the association of two or more receptors, which alone have either a low affinity or no affinity for the ligand, as shown for IL-6R, CNTFR, or leukemia inhibitory factor receptor (LIFR) (Miyajima et al., 1992).

BIOLOGICAL SYSTEMS FOR GROWTH FACTOR STUDIES

The *in vivo* investigations include work on tissue extracts, on tissue slices, and (by injection) on the living organism of normal or of transgenic animals. *In vitro*, different kinds of tissue cultures can be used, either primary cultures or cell lines. Primary cultures

TABLE 30-1. *Ubiquitous Growth Factors*

Factors	Full Names	Amino Acids	Receptors
EGF family			
EGF	Epidermal growth factor	53	EGFR
TGFα	Transforming growth factor α	50	EGFR
AR	Amphiregulin	78	EGFR
SGDF	Schwannoma-derived growth factor	(35)	EGFR
HB-EGF	Heparin-binding EGF-like growth factor	(22)	EGFR
HRGα/NDF	Heregulin/NEU differentiation factor	(45)	EGFR2/ErbB2
FGF family			
FGF-1 (aFGF)	(acidic) Fibroblast growth factor	140	FGFR1, -2, -3, -4
FGF-2 (bFGF)	(basic) Fibroblast growth factor	154	FGFR1, -2, -3
FGF-3 (int-2)		231	
FGF-4 (hst-1 or K-FGF)	Human stomach tumor gene-1 or Kaposi sarcoma FGF	148	FGFR1, -2
FGF-5		267	
FGF-6 (hst-2)	hst-1 related gene	208	
FGF-7 (KGF)	Keratinocyte growth factor	163	FGFR2
IGF family			
IGF-1	Insulin-like growth factor	70	IGF-1R
IGF-2		67	IGF-2R
Insulin		51	IR
PDGF family			
PDGF-AA	Platelet-derived growth factor	2×125	PDGFRα
PDGF-BB		2×114	PDGFRβ
PDGF-AB		114+125	PDGFRα-β
TGF-β family			
TGFβ1	Transforming growth factor β	2×112	TGFβRI, -II, -III
TGFβ2		2×112	TGFβRI, -II
TGFβ3		2×112	TGFβRI, -II, -III

TABLE 30-2. *Other Growth Factors Related to Glia*

Miscellaneous factors and active peptides	
	Thrombin
PA	Plasminogen activator
PD-ECGF	Platelet-derived endothelial cell GF
GMF	Glia maturation factor
ET-(1-3)	Endothelin (1 to 3)
VIP	Vasointestinal peptide
Neurotrophic factors	
NGF	Nerve growth factor
BDNF	Brain-derived neurotrophic factor
NT-(3-5)	Neurotrophin (3 to 5)
GDNF	Glia-derived neurotrophic factor
CNTF	Ciliary neurotrophic factor
CDF/LIF	Cholinergic differentiation factor or leukemia inhibitory factor
GDN	Glia-derived nexin
Cytokines	
IL-(1-13)	Interleukins
TNF(α/β)	Tumor necrosis factor
BCGF	B-cell growth factor
IFN(α-γ)	Interferon
Hematopoietic factors	
M-CSF	Macrophage CSF (or CSF-1)
GM-CSF	Granulocyte and macrophage CSF
G-CSF	Granulocyte CSF
IL-3	Multi-CSF or interleukin-3

CSF, colony stimulating factor

include explants, reaggregates, or dissociated monolayer cultures derived from embryos or young animals.

Astroblasts and Ependymal Cells in Monolayer Culture

Glial cell cultures are usually derived from brains of newborn rats. In most studies, astroblast (type 1) cultures have been obtained by growing the dissociated cells of newborn rat brain in a culture medium enriched with 10% fetal calf serum (for review see Sensenbrenner et al., 1986). These cells proliferate for 7 to 10 days and then become confluent as a monolayer of large flat cells. They mature as a function of time. For example, expression of glial fibrillary acidic protein (GFAP), S-100 protein, and glutamine synthetase (GS) begins after a few days *in vitro* and increases roughly between days 10 and 30 *in vitro*.

Cultures highly enriched in ependymal cells can be obtained from the same dissociated cells, but grown

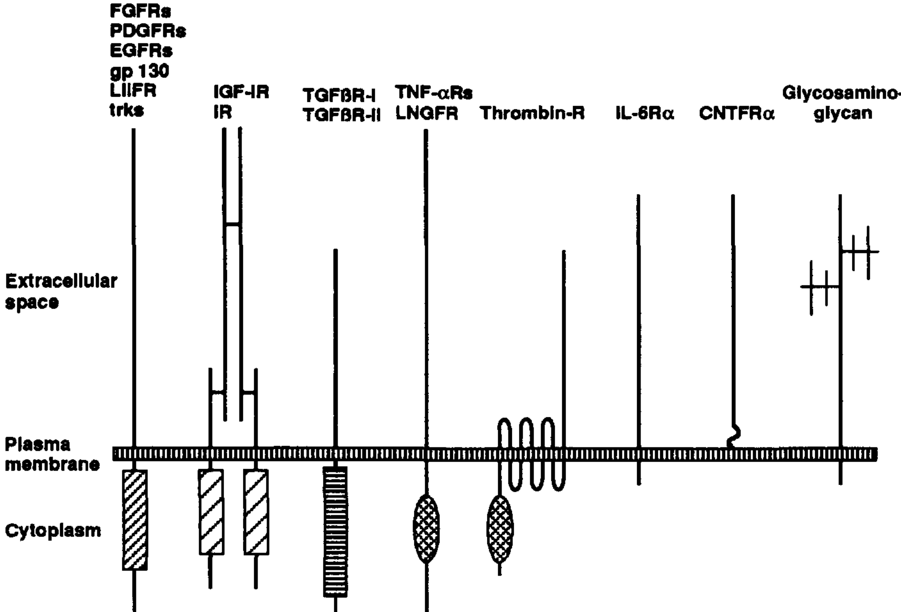

FIG. 30-1. Growth factor receptors and receptor complexes. In the cytoplasmic compartment, *obliquely hatched boxes* represent tyrosine kinase domains, the *horizontally hatched box* represents a serine-threonine kinase domain, the *ovals* represent domains interacting with G proteins.

in the absence of serum and in the presence of thrombin (Weibel et al., 1986).

Oligodendrocytes and Their Progenitors in Monolayer Mixed Culture

If dissociated cells from newborn rat brain are grown at high cell density and in the presence of 10% calf serum, small round cells appear on the monolayer of flat astroblasts (type 1) (Labourdette et al., 1979). They proliferate actively for about 2 weeks and then differentiate into oligodendrocytes and express progressively, over a period of 4 to 7 weeks, the various myelin markers: sulfatides, galactocerebrosides, cyclic nucleotide phosphohydrolase (CNP), myelin basic proteins (MBP), carbonic anhydrase type II, proteolipid protein (PLP), ceramide galactosyl sulfotransferase, ceramide sulfotransferase, and myelin-associated glycoprotein. Cultures derived from rat embryo optic nerve are enriched in oligodendrocytes and have been also extensively studied.

Glial Progenitor Cells in Pure Culture and Type 2 Astrocytes

The small, round cells described above can be detached selectively from the mixed glial culture by flushing culture medium on the cell layer or by rotary agitation for 16 to 24 hours. After about 10 days in such primary cultures the small cells are mostly bipotential precursor cells (also called O-2A progenitor cells), characterized by their reaction with the A2B5 monoclonal antibody. In secondary culture, they can differentiate either into oligodendrocytes if they are grown in the absence of serum, or into type-2 astrocytes in the presence of 20% fetal calf serum (Raff et al., 1983).

Oligodendrocytes

Oligodendrocytes can be obtained in culture either by the differentiation, in the absence of serum, of O-2A progenitor cells isolated as described in the previous section, or by the selective detachment of already mature cells from an aged mixed glial culture (after 30 days *in vitro* or more). They can also be obtained from brain of adult animals by an enzymatic dissociation of the cells, followed by a separation of the various cell types by centrifugation in a gradient of sucrose or of Percoll.

Brain Cell Reaggregates

Cells dissociated from fetal rats (usually 15-day-old), can form aggregates when they are maintained in flasks under constant rotary agitation (Honegger and Tenot-Sparti, 1992). In this culture system, cells are surrounded by a microenvironment resembling

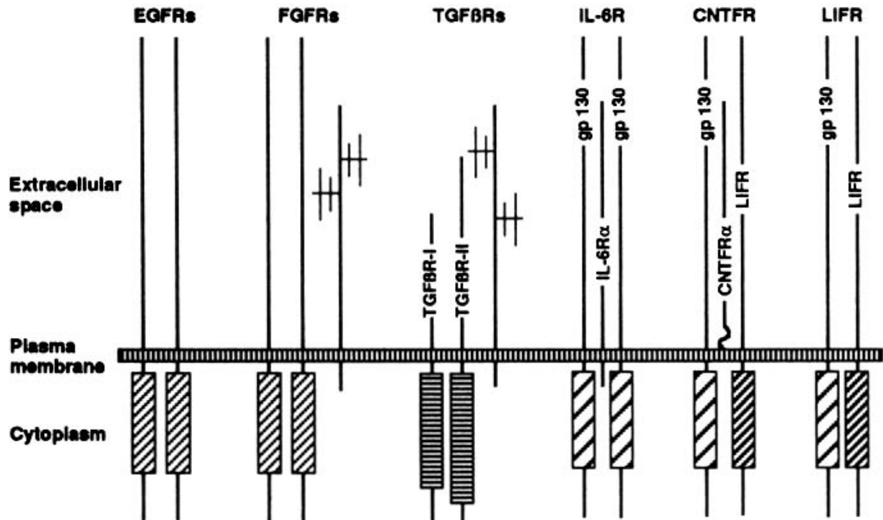

FIG. 30-2. Growth factor receptor complexes. Same specifications as in Figure 30-1.

that found *in vivo,* but which can be manipulated to some extent by modifying the culture medium.

Immortalized and Transformed Glial Cells

When primary cultures were not available cell lines derived from normal or transformed cells have been used. For instance, the C6 glioma cell line, derived from a nitrosourea-induced tumor, has been used as a model of astrocytes and of oligodendrocytes and the spontaneously immortalized CG4 cell line is used as a model of O-2A progenitor cells (Louis et al., 1993).

In glial tumors, the cells are not homogeneous. They can be grown as a mixture or they can be cloned to obtain only one tumoral cell type. Such cells are used mainly to study the mechanisms of transformation and the possible involvement of growth factors.

FIBROBLAST GROWTH FACTORS

On the basis of the hypothesis that soluble factors should participate in the development of cells of the central nervous system (CNS), it has been shown that soluble brain extracts from chick embryos are able to stimulate the morphological differentiation and the proliferation of astroblasts from chick embryos in dissociated primary culture (Sensenbrenner et al., 1972). Later on, acidic and basic fibroblast growth factor (aFGF and bFGF, also called FGF-1 and FGF-2, respectively) have been found to be the active molecules present in these soluble brain extracts (Pettmann et al., 1985).

Family Relationships

The two first identified fibroblast growth factors, aFGF and bFGF, have been purified to homogeneity from bovine pituitary gland and brain. They are composed of a single polypeptidic chain and share 55% amino acid sequence identities.

Five other structurally related FGFs (Table 30-1), with 35 to 55% sequence homology have been identified (for review see Baird and Klagsbrun, 1991). They differ from aFGF and bFGF by the presence of a signal peptide, glycosylation sides, expression only during embryonic development, and specific target cells.

Receptor Family

To date, a group of four transmembrane high-affinity receptors have been identified and designated as FGFR1, R2, R3, and R4 (for review see Partanen et al., 1992). The members of the FGF family have overlapping affinities for these receptors (Table 30-1).

Another class of binding sites for FGFs is related to heparin-like glycosaminoglycans (GAGs) and heparan sulfate proteoglycans (Figure 30-1). They have been shown to be required for bFGF and K-FGF to bind its high-affinity receptors (for review see Partanen et al., 1992) (Figure 30-2).

Cellular Localization in the Central Nervous System In Vivo *and* In Vitro

Acidic FGF and bFGF are widely and abundantly expressed in the developing and adult CNS of chick, mouse, rat, monkey, and human. FGF-5 is also pres-

ent in the central nervous system (Table 30-3). Most immunocytochemical staining experiments have revealed that aFGF and bFGF are associated with neurons *in vivo* and *in vitro*. However, aFGF, bFGF, and their mRNAs have also been found in astroglial cells (Tables 30-3 and 30-4). Acidic FGF has been localized in a subpopulation of ependymal cells and tanycytes, as well as in some glial cells of adult rat brain (Tooyama et al., 1991). In culture, rat and bovine brain astrocytes as well as mouse cerebellum astrocytes synthesize bFGF and to a much lesser extent also aFGF (Table 30-4). Several authors pointed out a nuclear localization of bFGF in astrocytes *in vivo* as well as *in vitro* (Cintra et al., 1991; Woodward et al., 1992) and of aFGF in oligodendroglial cells *in vivo* (Tourbah et al., 1991).

Although aFGF and bFGF lack a signal peptide sequence, a recent study has clearly indicated that bFGF-like peptides are released from both glial and neuronal cells *in vitro* (Araujo and Cotman, 1992). Furthermore, this release is differentially regulated by several lymphokines and other growth factors.

Cellular Localization of Receptors in the Central Nervous System and in Neural Cells In Vitro

The presence of high-affinity receptors for FGF has been reported in the CNS of adult bovine, rat, and guinea pig. FGF receptor mRNA is present in the developing chick, mouse, and rat brain. The expression of FGF receptor mRNA *in situ* has been found

to be high on a large number of specific neuronal populations in the embryonic as well as adult CNS. In contrast, glial cells *in situ* express no or few receptors (Wanaka et al., 1990).

In culture, it has been mentioned that cultured astroglial cells possess FGF receptors (Araujo and Cotman, 1992).

FGFR1, R2, and R3 are all expressed in brain, type-1 on neurons and type-2 on glial cells. Analysis of FGFR1 expression during mouse neurulation has shown high levels in the developing neuroectoderm and as development proceeded, this receptor expression became localized to neuronal precursors. In contrast, FGFR4 mRNA was never detected in the CNS.

The above-mentioned observations suggest that at least aFGF and bFGF and their receptors may be expressed by CNS neurons as well as glial cells.

Effects on Astroblast Proliferation

Fibroblast growth factors and many other growth factors (see also below) have been found to stimulate

the proliferation of quiescent astroblasts (Table 30-5). Acidic and basic FGFs are the most potent with thrombin and EGF. Their effect is transient, and under normal culture conditions they induce only one cell cycle.

Antisense bFGF oligodeoxyribonucleotides inhibit DNA synthesis of rat astrocytes (Gerdes et al., 1992). This result suggests that bFGF, in addition to its classical effect as a growth factor, is also an endogenous growth signal in developing astrocytes.

Effects on Astroblast Morphology and Maturation

FGFs and EGF, elicit a strong morphologic effect on astroblasts (Table 30-5). Their cell bodies shrink, giving rise to small, round cells with extended processes.

Several mitogenic growth factors, including FGFs, have been shown to stimulate the maturation of astroblasts–as determined by their upregulation of the glutamine synthetase (GS) activity and of the level of S-100 protein (Guenter-Lauber and Honegger, 1985; Perraud et al., 1988). These maturation effects follow the transient mitogenic effects of the factors (Loret et al., 1989).

The effects of these growth factors on the rate of synthesis of the various cell proteins have been investigated by using two-dimensional polyacrylamide gel electrophoresis. This method has shown that growth factors are able to modulate the rate of synthesis of many proteins (Table 30-5). This effect lasts for several days after the end of the DNA synthesis and varies with time (Loret et al., 1989).

Effects on O-2A Progenitor Cells and Oligodendrocytes

In subculture and in a chemically defined medium, O-2A progenitor cells and oligodendrocytes proliferate at a very low rate. Two families of growth factors have been found to strongly stimulate their proliferation: FGF and platelet-derived growth factor (PDGF) (Table 30-6). The effect of bFGF can last for several days if the treatment is renewed. Basic FGF also delays the differentiation of O-2A progenitor cells probably as a result of its mitogenic effect (McKinnon et al., 1990).

In reaggregates, bFGF does not elicit a significant mitogenic effect on the O-2A progenitors, but it stimulates cyclic nucleotide phosphohydrolase activity (Honegger and Tenot-Sparti, 1992).

Basic FGF is able to induce the proliferation of 12% of the oligodendrocytes isolated from adult rat brain if the cells were kept for at least 2 weeks *in vitro* (Vick and DeVries, 1992). In mature oligodendrocytes grown *in vitro,* bFGF also inhibits the expression of MBP transcripts (Fressinaud et al., 1995).

Fibroblast Growth Factors and Reactive Gliosis

Reactive gliosis occurs after CNS injury: astrocytes present in and around the area of wound react by a hyperplasia, migration toward the site of wound, and some proliferation. These reactive astrocytes then form a structurally organized posttraumatic glial scar. This subject is treated in Chapter 55, so we will just report some data about the possible involvement of FGF.

In response to a CNS lesion, FGF mRNA and protein levels are increased in macrophages, neurons, astrocytes, and vascular endothelial cells. Reactive astrocytes highly express bFGF within a week and aFGF only after 1 week (Tourbah et al., 1992). A specific expression of the FGFR1 mRNA occurs too.

The injection of bFGF in various brain areas of the neonatal rat after an electrolytic lesion results in an increase of the number of reactive astrocytes as soon as 3 days after injury (Eclancher et al., 1990). After 20 days, the astrocytes are packed in several layers along the borders of the lesion, thus reducing its extension. Similarly, the intraventricular administration of bFGF in adult rat brain after partial fimbria transection enhances the lesion-induced astroglial reaction by changing the morphology of the astrocytes and by increasing the number of the reactive astrocytes that proliferate. It is suggested that bFGF-promoted glial scar could be beneficial for wound repair and neural sprouting in the damaged brain.

EPIDERMAL GROWTH FACTOR

Family

The epidermal growth factor (EGF) family is composed of at least five factors that bind to the same receptor (Table 30-1). TGFα has been discovered (like TGFβ) as a molecule secreted by fibroblasts transformed by a retrovirus. EGF, TGFα, HB-EGF, and EGFR are present in brain (Table 30-3). TGFα is localized mainly in neurons but is also found in a subpopulation of astrocytes (Kudlow et al., 1989). The receptor is expressed in astrocytes and in ependymal cells (Birecree et al., 1991).

Effects on Glia

Westermark (1976) first reported that EGF was able to stimulate the proliferation of the human glial cell line 787CG. EGF also stimulates the proliferation of astroblasts in primary culture (Table 30-5). It induces a morphological transformation of these cells, stimulates the activity of GS, and modulates the rate of synthesis of many proteins (Loret et al., 1989).

A strong correlation has been found between tumor grade of glioblastomas and the extent of TGFα expression. High expression and structural abnormalities of the EGF receptor have been found to provide tumorigenic advantage for gliomas.

EGF has been reported to inhibit myelin basic protein expression in mature oligodendrocytes (Sheng et al., 1989) (Table 30-6).

PLATELET-DERIVED GROWTH FACTORS

Three platelet-derived growth factors (PDGFs) are known as combinations of two peptidic chains: AA, AB, and BB (Table 30-1). They have been discovered in the blood platelets from which they are released upon activation. These factors are found in various normal and transformed cells and stimulate mainly the growth of mesodermal cells. They are present in brain, mainly in neurons, but PDGF-AA mRNA is also weakly expressed in astrocytes *in vivo* (Table 30-3). *In vitro*, this factor is expressed and secreted by astrocytes (Table 30-4) and by oligodendrocytes.

Effects on Astroblasts

Under the effect of PDGFs, astroblasts in culture are induced to proliferate, they extend processes, but

much shorter than under the effect of FGF, and they increase their synthesis of thrombospondin, a 450 kD lectin-like protein. This factor elicits also a chemotactic effect on astroblasts *in vitro* (Table 30-5).

Trapidil, which is known as a specific antagonist of PDGF, is able to reduce gliosis, a result suggesting that PDGF is involved in this reaction.

Effects on O-2A Progenitors and Oligodendrocytes

PDGFs are mitogens for O-2A progenitor cells in monolayer cultures, but their effect is more transient than that of FGFs. PDGF-AA is more active than PDGF-BB on the growth of optic nerve O-2A progenitors. Like FGFs, PDGFs delay the differentiation of the progenitors (Table 30-6). The combination of FGF and PDGF is more efficient to maintain a high rate of proliferation and to inhibit O-2A differentiation (Bögler et al., 1990).

The mitogenic effect of astroblast-conditioned medium on O-2A progenitors appears to be due to PDGF (Noble et al., 1988). In mixed cultures of astroblasts and O-2A progenitor cells, the fast proliferation of O-2A progenitor cells and their low rate of differentiation may be due to the presence of serum in the culture medium but also to PDGF synthesized by type-1 astroblasts.

PDGF is not a mitogen for mature oligodendrocytes but it induces the expression of Fos and Jun proteins in these cells, suggesting an activation of the receptors. In reaggregates, PDGFs are weak mitogens for glia (unspecified) and they stimulate CNP (Honegger and Tenot-Sparti, 1992).

INSULIN-LIKE GROWTH FACTORS

The insulin-like growth factor family is composed of IGF-1, IGF-2, and also insulin, which is known as a hormone. These three factors are found mainly in serum. The two IGFs are produced at a high level by liver. IGF-1 and its receptor are synthesized in most tissues and cells, and in the brain in which a truncated form is found. IGF-2 mRNA was also found in brain, in choroid plexus, meninges, and vascular sheaths (Table 30-3). Its presence in astrocytes and ependymal cells is still controversial. *In vitro*, astrocytes synthesize IGF-1 and IGF-2 (Table 30-4). Insulin is present in brain, but its origin is not known (Wozniak et al., 1993).

The presence of IGF-1 or of insulin at a high level is required to keep the various glial cells surviving *in vitro*. However, the cells can survive for a few days without insulin. Under this condition, the mitogenic effects of the other growth factors are much lower. Moreover, the addition of anti-IGF-1 antibody to the culture medium prevents the mitogenic effect of EGF on astrocytes (Chernausek, 1993). Thus IGF-1 appears to be a cofactor of the mitogenic effects of the growth factors. Alone, IGF-1 is a weak

mitogen for astrocytes and oligodendrocyte O-2A progenitors, and promotes the differentiation of the latter cells into oligodendrocytes (Table 30-6). In oligodendroglial cells, it increases the level of expression of MBP, CNP, and glycerol-phosphate dehydrogenase (G3PDH) (van der Pal et al., 1988). A general effect of IGF-1 on oligodendrocytes is shown in transgenic mice overexpressing IGF-1. In these animals, the percentage of oligodendrocytes in brain is not modified, but the amount of myelin is increased by 130% (Carson et al., 1993).

C6 glioma cells expressing IGF-1 antisense RNA lose their tumorigenicity and prevent that of non-transfected C6 cells. This observation suggests that antisense blocking of IGF-1 expression may reverse a phenotype that allows C6 cells to evade the immune system (Trojan et al., 1993).

TRANSFORMING GROWTH FACTORS TYPE β

Family

TGFβ1 has been discovered as a molecule secreted with TGFα by fibroblasts transformed by retroviruses. It has the same primary structure in man, pig, bovine, and monkey, but in murine there is one different amino acid. This factor inhibits the growth of most cells, but it can be a mitogen for some other cells. Most, if not all, cells have receptors for TGFβs.

TGFβs and transcripts of the three isoforms (Table 30-1) are expressed in embryonic and adult mouse brain (Table 30-3), but the presence of TGFβ1 in neural cells is still debated. Astrocytes express the three forms *in vivo* as well as *in vitro* (Table 30-4).

Effects on Astroblasts

TGFβ1 inhibits the proliferation of astroblasts, but a stimulatory effect has also been reported (Table 30-5). It stimulates phosphoinositol metabolism and the translocation of protein kinase C (Robertson et al., 1988). In these cells, it potentiates the mitogenic effect of bFGF but not that of the other growth factors, and it inhibits transiently the morphologic effect of bFGF (Table 30-5).

Effects on O-2A Progenitor Cells

Alone, TGFβ1 stimulates weakly the proliferation of O-2A progenitor cells (Table 30-6). When it is combined with bFGF, its effect is bimodal. At low concentrations it potentiates the mitogenic effect of bFGF, and at higher concentrations it inhibits it (Besnard et al., 1989a).

NEUROTROPHIC FACTORS

Neurotrophic factors have been defined primarily as molecules involved in the regulation of a variety of neuronal developmental processes such as differentiation, survival, neurite outgrowth, and synaptic rearrangement.

In the adult CNS, glial cells do not express, or at relatively low levels, neurotrophic factors (such as CNTF and NGF) under normal conditions (Table 30-3). However, following injury the synthesis of such factors increases dramatically and transiently in the area around the wound site and become mainly localized in reactive astrocytes forming the glial scar. Growing astroglial cells in culture results in sustained expression of neurotrophic factors. Thus, astrocytes *in vitro* may behave just as the activated astrocytes *in vivo* by upregulating their levels of neurotrophic factors.

Neurotrophins and Their Receptors

As reported above, NGF, a basic 118-amino acid protein, was the first growth factor (actually a neurotrophic factor) discovered. Subsequently, several neurotrophic factors belonging to the family of NGF, called neurotrophins or neurokines, were characterized. These factors, brain-derived neurotrophic factor (BDNF), NT-3, NT-4, and NT-5, have a strong sequence homology, but they exhibit different neuronal specificity. All five neurotrophins are capable of promoting the survival and differentiation of sensory neurons of the peripheral nervous system. NGF is also a survival factor for sympathetic neurons. BDNF supports in addition retina ganglion cells, mesencephalic dopaminergic neurons and neural crest-derived sensory neurons. BDNF as well as NT-3 affect neurons of the nodose ganglion. Cholinergic neurons in the basal forebrain respond to both NGF and BDNF (for reviews, see Thoenen, 1991; Ebendal, 1992; see also Chapter 29, this volume). Recently, a new neurotrophic factor, GDNF (glial cell line-derived neurotrophic factor) has been characterized. It is active on midbrain dopaminergic neurons (Lin et al., 1993).

The first known NGF receptor was a low-affinity receptor (named $p75^{NGFR}$ or LNGFR, low-affinity nerve growth factor receptor or LANR, low-affinity neurotrophin receptor) acting probably through interaction with G proteins (Figure 30-1). Subsequently, the protooncogene *trk* (*trk*A), named

because of its tyrosine kinase activity, has been shown to be a high-affinity receptor for NGF. Later on, two other high-affinity receptors related to *trk* (*trk*B and *trk*C) have been cloned and characterized. LNGFR binds all neurotrophins while *trk*A binds NGF and NT-5, *trk*B binds BDNF and NT-3 to -5, and *trk*C binds NT-3. It seems that the low- and high-affinity receptors can act independently, triggering different biological effects; however, not all data fit with this view (for review see Meakin and Shooter, 1992).

The *trk*B receptors expressed by glial cells *in vivo* as well as *in vitro,* are truncated forms, lacking the tyrosine kinase domain (Frisén et al., 1993). The high expression of these truncated *trk*B receptors by glial cells in the intact nervous system and their altered expression after injury, as shown by an increase or decrease in the injured CNS or peripheral nervous system, respectively point out to a functionally important involvement of this nonneuronal NGF receptor in nerve regeneration.

The truncated forms of *trk*B and *trk*C, notably expressed in astrocytes, may act not as signaling receptors, but rather as neurotrophin-trapping molecules (Valenzuela et al., 1993).

In Vivo **Expression.** The members of the neurotrophin family show parallel as well as distinct patterns of regional expression in the CNS. The hippocampus and neocortex are the brain regions with the highest levels of NGF and BDNF. The largest amounts of NT-3 are found in the hippocampus and cerebellum (Table 30-3). These three neurotrophic factors are maximally expressed at different times of brain development in the rat (for review see Thoenen, 1991).

Nerve growth factor protein has been found to be predominantly localized in neurons of various brain areas. However, actively growing glial cells in the developing or injured CNS may as well synthesize NGF (Lu et al., 1991). Transection of the adult optic nerve, which is known to elicit increase in reactive glial cell number, evokes a marked and transient increase in NGF mRNA expression. Another study has demonstrated that after lesion of the septohippocampal pathways or by intraventricular administration of IL-1β, many astrocytes activated by both treatments become NGF-like immunoreactive in the septum and hippocampus (Oberfeld-Nowak et al., 1992). This expression does not appear to be related to proliferation.

In the CNS of the rat, NGF receptor mRNA and protein have been detected mainly in neurons during development. However, in the adult rat brain, NGF receptors have also been detected in ependymal cells and in nonnervous cells such as leptomeninges, epithelial cells of the plexus choroid and in the cerebral vessels (Delvalle et al., 1992). Another study (Frisen et al., 1992a) has shown that *trk*B mRNA as well as *trk*B protein-like immunoreactivity are increased in the rat and cat spinal cord after trauma, suggesting a role for these receptors in axonal sprouting. The *trk*B receptors have been localized to neurons, but also to astrocytes and leptomeningeal cells. However, as mentioned above, the *trk*B and *trk*C receptors expressed in glia are inactive forms.

In Vitro **Expression.** Cultured neuronal and glial cells (specifically astrocytes, Table 30-4) from a variety of brain areas express the mRNA for NGF and synthesize and secrete the protein (Zafra et al., 1992).

In culture, rat hypothalamic and cortical oligodendrocytes, a subpopulation of differentiated astrocytes, and a subpopulation of hypothalamic neurons express the NGF protein but at different levels (Gonzales et al., 1990) while NGF mRNA is expressed at similar levels by cortical type-1 astrocytes, oligodendrocyte progenitor cells and neurons. This observation suggests the existence of different posttranscriptional regulations in these cell types. In other culture systems, rat brain oligodendrocytes and microglial cells do not express NGF mRNA, and the message for NGF has only been detected in astrocytes (Spranger et al., 1990).

In low-density cultures, in which glial cells grow rapidly, the cells express high levels of NGF mRNA and as density increases with time, amounts of NGF mRNA decrease progressively. Thus, actively growing glia in culture may preferentially synthesize NGF.

Cultured rat hippocampal astrocytes have been found to express mRNA for NGF and NT-3 at significantly higher levels than cultured neuronal cells. However, NGF and NT-3 proteins are undetectable immunocytochemically. In contrast, these astrocytes do not express BDNF mRNA, but the message is detectable in the cultured hippocampal neurons (Rudge et al., 1992; Zafra et al., 1992).

The production of NGF by astrocytes in culture is extremely variable and can be regulated by many molecules (Table 30-4). The lymphokine interleukin-1 (IL-1) and several growth factors, such as EGF, aFGF, bFGF, TGFα, and TGFβ stimulate transiently the synthesis of NGF by cultured astrocytes (Spranger et al., 1990). The increase of NGF mRNA is reflected by a corresponding increase in NGF protein release into the culture medium (Spranger et al., 1990; Yoshida and Gage, 1991). It has been described that cytokines, such as IL-1 and TGFβ1 are without effect on BDNF and NGF mRNA levels in cultured neurons (Zafra et al., 1992). These authors also reported that all the cytokines and growth factors that produce a marked increase of NGF mRNA

in cultured astroglial cells are without effect on astrocyte BDNF mRNA levels. Thus, it seems that there are notable differences in the regulation of BDNF and NGF mRNA expression in cultured astrocytes.

Effects on Glia. Human fetal astrocytes do not express functional high-affinity NGF receptors (see the section *Neurotrophins and their Receptors* above) and do not respond to NGF. In contrast, NGF has been reported to induce proliferation and enhances fiber regeneration in mature oligodendrocytes from adult pig brain (Table 30-6).

Ciliary Neurotrophic Factor, Cholinergic Differentiation Factor/Leukemia Inhibitory Factor, and Interleukin-6

CNTF, CDF/LIF, and IL-6 (together with oncostatin M) are structurally related molecules which elicit overlapping effects on various cells. This characteristic appears to be due to the structure of their receptors (Figure 30-2), which are complexes sharing the gp130 tyrosine kinase. It seems that gp130 alone has no binding capacity for any of the three factors.

CNTF, a 20 to 24 kD acidic protein, has been first found and isolated from chick embryonic ocular tissue. This factor has been shown to support *in vitro* survival of parasympathetic ciliary ganglion neurons and of a variety of other peripheral neurons as well as CNS neurons. CDF/LIF has been purified by several groups under various names, since it elicits effects on cells in many organs. In the nervous system, this factor induces the cholinergic differentiation of mature sympathetic neurons. More details about IL-6 are given in the section *Cytokines and Hematopoietic Factors* below (seee also Chapter 46, this volume).

***In Vivo* and *In Vitro* Expression.** In the adult rat CNS, CNTF mRNA and protein levels are high in the olfactory bulb and optic nerve but barely detectable in the rest of the brain (Stöckli et al., 1991). CNTF immunoreactivity is restricted to a subpopulation of cells with an astrocyte-like morphology (Table 30-3). IL-6 is also localized in astrocytes *in vivo*. CDF/LIF is present in various areas of the brain, but its cellular localization has not yet been determined.

Astrocytes from newborn rat brain or hippocampus in culture express high levels of CNTF mRNA and protein. Expression of CDF/LIF has also been observed in astrocytes *in vitro*, and it is stimulated by other cytokines and LPS (Table 30-4).

The CNTF protein does not contain a secretion signal sequence, indicating that this molecule is not released, or not by the usual mechanism. However, in the denervated nerve, CNTF was found to be localized extracellularly and may play an important role during neurite outgrowth (Sendtner et al., 1992; see also Chapter 29, this volume).

Effects on O-2A Progenitors and Oligodendrocytes. *In vitro*, CNTF induces bipotential glial O-2A progenitor cells of rat optic nerve and brain to differentiate into type-2 astrocytes, and more efficiently in cooperation with extracellular matrix-associated molecules (Lillien et al., 1990). CNTF also protects oligodendrocytes against death *in vitro* (Table 30-6).

ENDOTHELINS

Endothelin (ET) was first characterized as a vasoconstrictor peptide produced by endothelial cells (see also Chapter 24). It stimulates DNA synthesis in vascular smooth muscle cells. Three highly homologous peptides have been identified.

Endothelins and binding sites are found in brain, in neurons, and in glial cells (Table 30-3). *In vitro*, astrocytes produce ET-1 and ET-3 (Table 30-5) and their receptors (Ehrenreich et al., 1991a). Endothelins elicit various effects on astrocytes including proliferation (Table 30-5). Of particular interest is their stimulatory effect on NGF (Table 30-4) and c-*fos* expression (Ladenheim et al., 1993).

THROMBIN

The thrombin molecule was first known as a protease, secreted by blood platelets and acting on the blood clotting. It is also a growth factor with a mitogenic activity toward fibroblasts, macrophages and endothelial cells. Its receptor has been recently characterized and cloned. Thrombin and its receptor are expressed in brain and only in neurons (Table 30-3).

Thrombin is a mitogen for astroblasts (Table 30-5) and stimulates S6 kinase through a protein kinase C-dependent mechanism and stimulates the activity of GS (Loret et al., 1989). In contrast to the effects of FGF and EGF which make the cells fibrous, after treatment with thrombin astroblasts are flatter than without treatment. Thrombin also reverses the stellation induced by dibutyryl cyclic AMP (Table 30-5).

GLIA MATURATION FACTOR

The glia maturation factor (GMF), a 17 kD acidic protein, has been first purified from pig brain. It stimulates the morphological and chemical matura-

tion and the proliferation of rat astroglial cells in culture (Table 30-5).

GMF is synthesized mainly in the nervous system. By using a monoclonal antibody, GMF has been localized in rat spinal cord astrocytes and rat cerebellum Bergman glia (Lim et al., 1987a). The presence of GMF in glial cells has been confirmed by a study on cultured rat brain astroglial cells (Lim et al., 1987b). In contrast, a polyclonal antibody developed against recombinant human GMF has been found to stain astrocytes and neurons as well (Table 30-3). Thus, GMF could mediate communication among astrocytes, among neurons, and/or between neurons and astrocytes.

PLATELET-DERIVED ENDOTHELIAL CELL GROWTH FACTOR OR GLIOSTATIN

Gliostatin, a polypeptide of two 50 kD chains, inhibits the growth of astrocytes *in vitro* (Table 30-5). Further work has shown that gliostatin is identical to PD-ECGF (Asai et al., 1992b).

CYTOKINES AND HEMATOPOIETIC FACTORS

Section IX of this volume is devoted to glia as part of the immune system so we will give only a few data in this field.

Interleukins are polypeptide factors acting as intermediates between leukocytes, but some of them like IL-1, IL-3, and IL-6 are also involved in other systems and particularly in the nervous system in which their functions seem to be specific.

IL-1 is synthesized by various cells and is responsible for the reactions of the organism to inflammation.

TNFα has been isolated from the serum of mouse treated with LPS (bacterial lipopolysaccharides) on the basis of its necrotic action on mouse sarcomas. This immunoregulator is produced mainly by lymphocytes and macrophages. *In vitro,* TNF-α is in most cases an inhibitor of cell growth. All cells, with the exception of red blood cells, express TNF-α receptors.

Colony stimulating factors (CSF) are mainly involved in the control of the development of hematopoietic cells.

Astrocytes and Cytokines

Astrocytes are immunocompetent cells that could participate locally to immunological reactions. In mouse brain infected with trypanosoma, the astrocytes express GM-CSF, TNFα, IL-6, IFNγ, and higher levels of IL-1α (Hunter et al., 1992).

In vitro, IL-1 and TNFα stimulate the proliferation of astrocytes and elicit various effects on these cells (Tables 30-4 and 30-5).

Astrocytes activated by endotoxins, viruses, and the cytokines IL-1, TNFα, and IFNs, produce several interleukins, the three CSFs, and on occasion TNFα and IFNs (Table 30-4). The expression of MHC-II is induced by TNFα and IFNγ. M-CSF is expressed in normal cultured astrocytes. TNFα, IL-1, and LPS stimulate its expression through a posttranscriptional regulation (Frei et al., 1992).

TNFα induces the expression of several adhesion molecules and of their mRNAs in cultured human fetal astrocytes (Table 30-5). Thus, in inflammatory conditions, the expression of these molecules by the astrocytes could facilitate the migration of leukocytes and contribute to the development of diseases like multiple sclerosis (Hurwitz et al., 1992).

Many astrocytoma and glioblastoma cells express and release IL-6 *in vitro* and *in vivo.*

High concentration of IL-2 stimulates the proliferation of O-2A progenitor cells (Table 30-6). IL-1 increases the number of IL-2 receptors in these cells. TNFα induces the death of oligodendrocytes *in vitro.*

B Cell Growth Factor

B cell growth factor is a T cell-derived lymphokine. It induces the growth of rat astrocytes, elicits a morphological effect on these cells, and enhances the level of GFAP mRNA (Table 30-5).

PUTATIVE FUNCTIONS OF GROWTH FACTORS IN THE CENTRAL NERVOUS SYSTEM

In a pluricellular organism, the behavior of every cell is governed exclusively by interactive processes between the signals it receives from the outside and its genetic program. Such interplay will differ somehow in the three different physiological conditions a cell will face: development, adulthood, and trauma. Growth factors are probably the main signals involved in these interactions, in addition to other soluble or insoluble molecules, and to direct intercellular contacts. The expression and the reception of some of these other signals and intercellular contact molecules can also be regulated by growth factors. The variety of the growth factors, their receptors, their localization, their direct and indirect effects on the cells, and the timing of their expressions in the

central nervous system can generate a tremendous number of combinations in space and in time. This number of possibilities is compatible with the highly specific and punctual actions required for the formation and maintenance of a complicated structure like the brain.

Involvement of growth factors in the development of the central nervous system is suggested by variations of their expressions and their receptors with time. Such an involvement is probable, as seen by the effects of growth factors on developmental processes like proliferation, differentiation, and morphological effects on nerve cells in culture. It is directly shown, for instance, by the greater development of brain in IGF-1 transgenic mice, compared to normal animals.

Involvement of growth factors in the adult brain is suggested also by the presence of various growth factors and by various observations concerning the maintenance, functioning, and plasticity of the brain. For example, as reported before, an increase of NGF concentration is found in hippocampus of male mice after fighting. Also, an increase in aFGF production and release by ependymal cells follows food intake by mice and that increase participates in the induction of the subsequent feeding avoidance.

Involvement of growth factors in response to trauma is likely, considering all the data available on that subject. After injury, several growth factors that are not produced in the normal brain are specifically synthesized and released at the site of injury and around it, and some of them are involved in the immunological defense. Intracerebral injections of some growth factors can improve neuronal survival or can mimic or enhance reactive gliosis. On the other hand, intracerebral injections of growth factor antagonists or antibodies can reduce or modify glial responses.

31 Effects of nerve impulses on glial membranes

RICHARD K. ORKAND

Coordination of glial cell function with neuronal activity requires mechanisms whereby neurons signal their behavior to the glial cells and affect their activity. The idea of neuron-glia interactions can be traced at least to Ramón y Cajal in 1895, who proposed a role for glial cells in higher nervous system function, based on his observations suggesting glial motility:

> The unpredictable turns that associations sometimes take—the fading away of ideas and words, the momentary halting of speech, the obsessive persistence of memory, the repression of an idea or experience as well as all types of erroneous motor reactions and other psychological function can be understood . . . by supposing the neuroglia of the gray matter serve as an insulating switching mechanism for nervous currents, permitting connections when they are active, and acting as insulators during repose (Ramón y Cajal, 1895, cited by Galambos, 1971).

Over longer times, such as those that are important during development (Chapters 27 and 49), myelination (Chapter 40), regeneration (Section XI), degeneration, and the activation of early response genes (Chapter 35), such signals, although not always well defined, must exist; they are discussed elsewhere in this volume. The possibility of relatively rapid effects of neurons on glial cells, which are important to glial function, becomes stronger as data accumulate, indicating that glial cells possess receptors for a number of small molecules which behave as transmitters or modulators at conventional synapses (see Section IV). Moreover, as it becomes clear that these potential messengers may be released from glial cells under appropriate conditions, the possibility of rapid signals from glial cells to axons must also be considered. It is well established that glial cells communicate with each other via gap junctions, which permit the exchange of ions and small molecules (Chapters 17 and 19).

This chapter deals mainly with possible interactions resulting from nerve impulse activity that are effective during shorter periods (seconds and minutes) and that might provide a signal for glial cells to function in the homeostasis of the neuronal microenvironment with regard to ions and small molecules. Among these homeostatic functions are the roles of glial cells in potassium regulation (Chapters 18 and 47), transmitter removal (Chapter 48), release of substrates (Chapter 52), and the buffering of extracellular pH (Chapter 14).

ANATOMICAL RELATIONS

Usually the membranes of glial cells and neurons are separated by narrow extracellular clefts, of the order of 15 nm wide, which form an intersecting network of sheetlike spaces (Chapter 26). This fluid space permits the diffusion of ions and small molecules between and among the two cell types. Thus, a substance released from one cell may readily affect another, depending on the diffusion coefficient for the particular substance in the space, the ability of the cells to modify the concentration of the substance through uptake or metabolism, the availability of receptors, and the resulting concentration of the substance at the receptor sites (Nicholson and Rice, 1991). Therefore, to consider whether a substance released from neurons has an effect on glial cells we need to consider the amount of the substance released from the neuron, the fate of the substance in the extracellular space, the availability of receptors on the glial cells, and the concentration of the substance reaching the glial receptors. Figure 31-1 depicts the anatomical relations of the cells of the central nervous system of vertebrates.

Special Cases

The anatomical relations between glial cells and neurons are highly specialized in the case of the ensheathement of axons by oligodendrocytes to form myelin (Chapter 40). At the nodes of Ranvier the terminal loops formed by oligodendrocyte membrane come in close contact with the axon and form an especially
