The modified version of Lee model code is used in numerical experiments for characterizing and optimizing neon soft X-ray yield ($Y_{sxr}$) of the United Nations University/International Center for Theoretical Physics Plasma Focus Facility (UNU/ICTP PFF) device operated at 14 kV and 30 µF. In our present work, the neon yield $Y_{sxr}$ is improved with an optimized UNU/ICTP PFF device by computing the

optimum combination of static inductance ($L_0$), anode length ($z_0$), anode radius ($a$) and cathode radius ($b$), keeping fixed their ratio ($c = b/a$) at 3.368, through a lot of numerical experiments at six operating pressures ($P_0$). At lower $P_0$ (e.g. 2.0, 2.5 and 3.3 Torr), the optimum $L_0$ value, together with the corresponding optimum combination of $z_0$, $a$ and $b$, is found to be 15 nH, whereas at higher $P_0$ (e.g. 4.0, 5.0 and 6.0 Torr), it is obtained as 10 nH. Though the computed maximum neon yield $Y_{sxr}$ (57.2 J with the corresponding efficiency of 1.94%) is found at $P_0 = 4.0$ Torr, assuming an achievable range of incorporating low-inductance technology, the best optimum combination of $L_0$, $z_0$, $a$ and $b$ is found to be at $P_0 = 3.3$ Torr, resulting in the computed optimum neon yield $Y_{sxr}$ of 54.6 J with a corresponding efficiency of 1.9%. This computed neon yield $Y_{sxr}$ is about 11 times higher than the measured value (5.4 ± 1 J) at optimum $P_0 = 3.5$ Torr for optimum anode configuration of this machine. In addition, neon yield $Y_{sxr}$ is obtained with our optimized combination of $L_0$, $z_0$, $a$ and $b$ at 11.5 kV and compared with the measured neon yield $Y_{sxr}$ of the NX2 machine.

1. Introduction

The dense plasma focus (DPF) device is a non-radioactive co-axial accelerator with relatively simple operating principle that produces a high-density, high-temperature plasma along with pulsed fusion neutron yield, soft and hard X-rays, high-energy electrons and ion beams and electromagnetic waves. This device is easy to construct, requires minimum maintenance and cost. The pulsed X-ray emitted from it has the highest intensity among all other existing devices of equivalent operating energy. The DPF device as a high-intensity pulsed X-ray source has a wide range of real-life applications such as in X-ray spectroscopy, X-ray microscopy and lithography, X-ray laser pumping, X-ray crystallography, X-ray radiography, X-ray back-lighter and X-ray micromachining. The United Nations University/International Center for Theoretical Physics Plasma Focus Facility (UNU/ICTP PFF) is a 3.3-kJ Mather-type DPF machine which is switched by a parallel-plate cascade air gap, powered by a 15-kV and 30-µF Maxwell capacitor. With support from the UNU and ICTP, the UNU Training Programme in Plasma and Laser Technology developed this device to initiate and promote practical knowledge and skills in plasma physics as well as fusion, in developing countries. This machine produces realistic focusing action operating in several gases (He, Ne, Ar, H2, CO2, D2, N2, etc.). The neon yield $Y_{sxr}$ for optimized DPF with operating energy in the range of 0.2 kJ–1 MJ was computed through numerical experiments by the Lee model code and it is observed that neon is a suitable operating gas for the device as a source of soft X-ray yield. The Lee model code is used to compute the realistic focus parameters along with the soft X-ray yield by only adjusting the computed discharge current waveform with the experimentally measured current waveform. In the case of NX2 DPF machine, this code has been successfully used showing
Neon soft X-ray yield optimization in a low-energy DPF device

a reasonably good agreement between the computed and measured values of neon yield $Y_{sxr}$ as a function of pressure.\textsuperscript{4} Therefore, the Lee model code is used to compute and optimize a DPF machine for improving the realistic yield $Y_{sxr}$.

For enhancing X-ray yields from the DPF device, many efforts have been made by changing the bank, tube and operating parameters such as energy of the bank, static circuit inductance, discharge current, electrode configuration (shape and materials), insulator materials and dimensions, gas composition and gas pressure.\textsuperscript{16} There is a combined drive parameter (speed factor) $(I_{\text{peak}}/a)/\sqrt{\rho}$, in which $I_{\text{peak}}$ is the peak discharge current and $\rho$ is the ambient gas density, which is one of the most important parameters that determine the performance of a DPF as a source of different types of energetic particles and radiations. The drive parameter also known as the speed factor (SF) is a fundamental scaling parameter that determines the characteristic axial speed and characteristic radial speed of the plasma focus when correctly formulated as an electromagnetic device. The Mather-type DPF devices with a wide range of energies ($E_0$) from few kJ to hundreds of kJ operated in neutron-optimized regime have a remarkably constant drive parameter $(89 \pm 9) \text{kA/(cm} \cdot \text{Torr)}$\textsuperscript{17} when operated in deuterium.\textsuperscript{17} The constancy of this parameter is related to the observation that in optimized devices the peak axial speed varies little from 10 cm/ms. This constancy of this parameter has been considered as a design tool of a DPF machine for neutron production in deuterium.\textsuperscript{18–20} For a neon plasma focus designed for optimum yield of characteristic neon soft X-ray, the drive parameter plays a dominant role also, since the pinch plasma needs to be within a temperature window\textsuperscript{15,18} required for the neon to be ionized to a combination of hydrogen-like and helium-like plasma. This places a requirement of on-axis radial shock speed and hence on the SF, although the requirement on the SF for neutron yield in deuterium and for characteristic soft X-ray yield will not necessarily be the same, due to the difference in the mechanisms of production of D-D neutrons and neon soft X-rays. Nevertheless a study of the range of drive parameters for good soft X-ray yields is useful and hence the values are also recorded in the present study.

The measured value of neon yield $Y_{sxr}$ from UNU/ICTP PFF was $(5.4 \pm 1)$ J at an optimum pressure of 3.0 Torr with the corresponding efficiency of 0.18%\textsuperscript{2}. The numerical experiment on this device was carried out using Lee model code to compute the optimum neon yield $Y_{sxr}$ keeping the cathode radius $b$ fixed at 3.2 cm, the anode length $z_0$ was drastically decreased from 16 cm to 7 cm, while the anode radius $a$ was slightly increased from 0.95 cm to 1.2 cm from the standard configuration. As a result, the neon yield $Y_{sxr}$ increased to 9.5 J at optimum pressure of 3.5 Torr with the corresponding efficiency of 0.32%\textsuperscript{13}. This computed efficiency of neon yield $Y_{sxr}$ got improved 2–3 times from the experimental value (0.18%) of the standard UNU/ICTP PFF.

Using the Lee model code, around 1994, Liu in his Ph.D. thesis\textsuperscript{2} took an initiative to improve the yield of characteristic line X-ray from UNU/ICTP PFF.
One of the conclusions of his research work was that the reduction of $L_0$ down to 10 nH improved the percentage of stored energy ($E_0$) going into the plasma with a corresponding increase in Ne line yield.\textsuperscript{2} This led to the design of a 16-Hz, 3-kJ, $L_0 = 12$ nH (best then possible) DPF built by AASC in the US, finally shipped and assembled at NIE. This machine\textsuperscript{4} is now known as the NX2.

In this paper, the $L_0$ along with its corresponding electrode geometry ($z_0$, $a$ and $b$) of the UNU/ICTP PFF machine is further optimized at 14 kV under different operating $P_0$ using the modified version of Lee model code to enhance the neon yield $Y_{sxr}$. Then neon yield $Y_{sxr}$ are computed with our optimized combination of $L_0$, $z_0$, $a$ and $b$ at 11.5 kV and compared with the measured neon yield $Y_{sxr}$ of the NX2 machine at 11.5 kV.

In this paper, Sec. 2 describes the Lee model code, whereas Sec. 3 describes the method of numerical experiment. The detailed description of numerical experiment for our optimization exercise is given in Sec. 4. Section 5 explains the process of finding optimum static inductance with its corresponding electrode configuration for possible maximum neon yield $Y_{sxr}$ in our optimization.

## 2. Lee Model Code

The electrical circuit and plasma focus dynamics, thermodynamics (specific heat ratio and charge number as a function of temperature) and radiations are coupled by the “Lee model code” which enables a realistic simulation that helps analyze all of the gross properties and performances of a DPF machine.\textsuperscript{18} This code is used in the interpretation of experiments and design of a DPF.\textsuperscript{20} An improved five-phase code incorporating finite small disturbance speed, radiation and radiation-coupled dynamics was used\textsuperscript{14} and was first published\textsuperscript{21} in the Web in 2000. Plasma self-absorption was included\textsuperscript{18,21} in 2007 improving the soft X-ray simulation with neon, argon and xenon among other gases. It has been widely used as a complementary facility in several machines, such as UNU/ICTP PFF\textsuperscript{4,12} NX1 and NX2\textsuperscript{4} as well as DENA.\textsuperscript{21} It has also been used in other machines for the design and interpretation including sub-kJ DPF machines,\textsuperscript{22} FNII,\textsuperscript{23} the UBA hard X-ray source,\textsuperscript{24} KSU PF\textsuperscript{25} and a cascading DPF.\textsuperscript{26} Computed information from Lee model code includes axial and radial speeds and dynamics,\textsuperscript{12,25} focus pinch duration and dimensions, average pinch temperatures and densities, soft X-ray characteristics and yield,\textsuperscript{4,13} optimization of machines and adaptation with modified Lee model code for Filipov-type DPF devices.\textsuperscript{21} The modified six-phase version of the Lee model code RADPFV6.1b is developed for Type-2 (high-inductance DPF) machines which have been found to be incompletely fitted with the five-phase model due to a dominant anomalous resistance phase.\textsuperscript{27}

In the Lee model code, the rate of neon line radiation is calculated as follows:\textsuperscript{18}

$$\frac{dQ_L}{dt} = -4.6 \times 10^{-31} n_i^2 Z Z_{n}^4 (\pi r_p^2) z_{\text{max}} / T ,$$  

where $Q_L$ is the neon line radiation, $Z_n$ is the atomic number, $Z$ is the effective
Neon soft X-ray yield optimization in a low-energy DPF device

charge number, \(n_i\) is the number density, \(r_p\) the pinch radius, \(z_{max}\) is the pinch column length and \(T\) is the average temperature of pinch plasma. In the calculation of the code, \(Q_L\) is computed by integrating over the pinch duration. The neon yield \(Y_{sxr}\) must be equivalent to the line radiation yield, i.e. \(Q_L = Y_{sxr}\), within the temperature window of 200–500 eV \((2.32 \times 10^6–5.8 \times 10^6\ K)\) which corresponds to an end axial speed of 6–7 cm/µs in the modified Lee model code.\(^2\) Within this temperature range the ionization level of neon is such as to make it hydrogen-like or helium-like, so that the plasma emits the characteristic line radiation of neon.

3. Method of Numerical Experiment

The measured discharge current waveform is a significant indicator to realistically simulate and analyze all the gross performances of any DPF. Important information such as the axial and radial phase dynamics, temperature and thermodynamic properties, the crucial energy transfer into the focus pinch that causes nuclear fusion and hence the radiation yields from the device are quickly traced out from the current waveform.\(^2\) This is why the discharge current waveform fitting is one of the best important techniques to optimize and configure a DPF. So, the fitting of the computed discharge current waveform to the measured current waveform through numerical experiment using Lee model code provides a lot of valuable insights of the pinched plasma.

First of all, the measured discharge current waveform is collected either from laboratory experiment or picked out from published literature. At the beginning of the numerical experiments, the code is configured for that DPF by providing the tube parameters, namely \(z_0\), \(a\) and \(b\); the bank parameters, namely the external static inductance \(L_0\), capacitance of the capacitor bank \(C_0\) and stray circuit resistance \(r_0\); and the operating parameters, namely voltage \(V_0\), \(P_0\) and the fill gas.\(^1,2,20\)

Then, the computed total discharge current waveform is fitted to the measured waveform by sequential adjustment of the four model parameters: mass swept-up factor \((f_m)\), plasma current factor \((f_c)\) in the axial phase and accordingly the radial mass factor \((f_{mr})\) and radial current factor \((f_{cr})\) in the radial phase. During the first initiative of fitting, the values of axial model parameters \(f_m\) and \(f_c\) are adjusted in such a manner that the rising slopes of computed current waveform and peak discharge current are in reasonable agreement with the measured total current waveform. Then the radial model parameters \(f_{mr}\) and \(f_{cr}\) are varied until the computed slope deeply fits with the measured values.\(^1\)

4. Numerical Experiments on UNU/ICTP PFF with Neon Filling Gas

To start the numerical experiments, the modified version of Lee model code (RADPFV5.15de) is configured for the UNU/ICTP PFF with the following published parameters\(^13\).
Fig. 1. Measured discharge current waveform of the UNU/ICTP PFF operated at 14 kV, 30 µF and 2.8 Torr with neon gas.

Fig. 2. Fitting of the measured current waveform (dotted line) with the computed current waveform (solid line) of UNU/ICTP PFF operated at 14 kV, 30 µF and 2.8 Torr with neon gas.

- Bank parameters: $L_0 = 110$ nH, $C_0 = 30$ µF and $r_0 = 12$ mΩ.
- Tube parameters: $b = 3.2$ cm, $a = 0.95$ cm and $z_0 = 16$ cm.
- Operating parameters: $V_0 = 14$ kV, neon gas (MW = 20, $A = 10$ and At-1 mol-2 = 1) and $P_0 = 2.8$ Torr.

A measured discharge current waveform of the UNU/ICTP PFF operated at 14 kV, 30 µF and 2.8 Torr with neon gas has been collected from the published waveform (see Ref. 28), presented in Fig. 1.

A reasonably good adjustment (Fig. 2) of the computed total discharge current waveform with the measured current waveform has been obtained with the following model parameters: $f_m = 0.05, f_c = 0.7, f_{mr} = 0.2$ and $f_{cr} = 0.8$. 
These fitted values of the model parameters are kept constant in all of our present numerical experiments for this paper.

The effects of $P_0$ on neon yield $Y_{sxr}$ emission from the device have been observed keeping fixed all of the above-mentioned bank, tube and operating parameters. In these numerical experiments, the pressure was varied in the range of 1.0–5.2 Torr and computed results are presented in Fig. 3.

From Fig. 3, it is observed that the neon yield $Y_{sxr}$ increases with increasing gas pressure until it reaches the maximum value of about 3.92 J at $P_0 = 3.3$ Torr with the corresponding efficiency of 0.13% after which it decreases with further increase of the pressure.

At this optimum pressure ($P_0 = 3.3$ Torr), the computed end axial speed is $v_a = 5.4$ cm/µs, the total peak discharge current is $I_{peak} = 180$ kA, the pinch current is $I_{pinch} = 103$ kA and the focusing time is about 3.97 µs. It is also noticed that the focusing time increases with increasing $P_0$. This is because higher the gas pressure, lower the current sheath (CS) velocity in both axial and radial phases and hence the focus time becomes slower with increase in gas pressure.

The characteristics of the variation of neon yield $Y_{sxr}$ with pressure depend on two major factors that are given below:

- First, at the computed optimum $P_0$, the $v_a$ of CS is about 5.4 cm/µs, which corresponds to the pinch temperature of $2.04 \times 10^6$ K. This temperature is very close to the correct pinch temperature window for the optimum neon yield $Y_{sxr}$ emission.
- Second, the radiation yield is proportional to the square of the plasma density. When the pressure is increased from a low value, the density of the pinched radiating plasma increases and as a result the X-ray emission increases. Thus, at
very low pressure the pinch plasma density is too low while the pinch temperature is very high due to high CS velocity. On the other hand, at very high pressure the pinch plasma density would be high and also the corresponding pinch temperature will be too low because of low CS velocity. In both cases, the pinch temperature may be away from the temperature window and hence the emitted neon yield $Y_{srx}$ is low.

Therefore, there would be an optimum pressure at which the pinch temperature and the corresponding end axial CS velocity are within the expected range while the density is still high enough for getting the maximum neon yield $Y_{srx}$ as shown in Fig. 3.

The measured values of neon yield $Y_{srx}$ from UNU/ICTP PFF have been obtained by Liu\textsuperscript{2} using a five-channel PIN soft X-ray detector confirmed by a calorimeter. In this experiment, the maximum value of neon yield $Y_{srx}$ from this device was found to be about $(5.4 \pm 1)$ J at the optimum pressure of $P_0 = 3.0$ Torr with the corresponding efficiency of 0.18%. At this optimum $P_0$, the typical values are as follows: end axial speed is $v_a = 5.7$ cm/$\mu$s, the total peak discharge current is $I_{peak} = 180$ kA and the pinch current is $I_{pinch} = 111$ kA.

In addition, many numerical experiments have been carried out to observe the effect of applied voltage on the neon yield $Y_{srx}$ from UNU/ICTP PFF versus the pressure. The variations of neon yield $Y_{srx}$ with pressure from this device are plotted at applied voltages of 12, 13, 14 and 15 kV as shown in Fig. 4.

From Fig. 4, it is observed that at optimum $P_0$, the neon yield $Y_{srx}$ rises from 2.74 J to 4.49 J with increasing the applied voltage from 12 kV to 15 kV. It is also noticed that for all applied voltages, the general nature of variations of neon yield $Y_{srx}$ with pressure is almost the same, but the optimum pressure values shift to higher ones with increasing the operating voltages.

![Fig. 4. Variations of computed neon yield $Y_{srx}$ from UNU/ICTP PFF versus pressure at different operating voltages.](image-url)
The anode geometry \((a \text{ and } z_0)\) along with the operating \(P_0\) of UNU/ICTP PFF has also been optimized through numerical experiments using the Lee model code, keeping fixed \(b\) at its standard value of 3.2 cm for enhancing the neon yield \(Y_{sxr}\). During this practical optimization, \(z_0\) is reduced drastically from 16 cm to 7 cm; \(a\) is increased from 0.95 cm to 1.2 cm. During this optimum anode configuration, the computed values are: \(v_a = 4.9 \text{ cm/\mu s}, I_{\text{peak}} = 184 \text{ kA}, I_{\text{pinch}} = 141 \text{ kA} \) and the neon yield \(Y_{sxr}\) is about 9.5 J at an optimum \(P_0 = 3.5\) Torr with the corresponding efficiency of 0.32%. It is found from these observations that the neon yield \(Y_{sxr}\) (9.5 J) at the optimum combination of \(a, z_0\) and \(P_0\) increases 2–3 times from the measured value (5.4 ± 1 J) at the optimum \(P_0\) of standard UNU/ICTP PFF configuration. It this case the corresponding \(I_{\text{pinch}}\) also increases from 111 kA (typical value) to 141 kA (computed).

It is noticed that with only pressure optimization of the machine, the computed neon yield \(Y_{sxr}\) (3.92 J) at the optimum pressure decreases from both the measured value and the value after \(a\) and \(z_0\) optimization, while \(I_{\text{pinch}}\) reduces to 103 kA. Therefore, it may be concluded that enhancing the neon yield \(Y_{sxr}\) by further increasing \(I_{\text{pinch}}\) is found to be a suitable technique. In the next section, we will discuss the technique for increasing \(I_{\text{pinch}}\) along with improving the neon yield \(Y_{sxr}\).

5. Optimization of \(L_0\) Along with Electrode Geometry at Different \(P_0\)

At the standard configuration of UNU/ICTP PFF device, the reduction effects of \(L_0\) on discharge current waveforms with time are observed through numerical experiments at \(P_0 = 3.3\) Torr of neon gas. The computed results are presented in Fig. 5.

It is found from Fig. 5 that \(I_{\text{peak}}\) comes earlier and also its value increases for each reduction of \(L_0\), consequently \(I_{\text{pinch}}\) will increase. For example, when \(L_0 = \)
30 nH, \(I_{\text{peak}} = 318.45\) kA at 1.28 \(\mu\)s, when \(L_0 = 20\) nH, \(I_{\text{peak}} = 368.11\) kA at 1.02 \(\mu\)s, when \(L_0 = 10\) nH, \(I_{\text{peak}} = 453.91\) kA at 0.60 \(\mu\)s, when \(L_0 = 5\) nH, \(I_{\text{peak}} = 508.44\) kA at 0.31 \(\mu\)s and when \(L_0 = 3\) nH, \(I_{\text{peak}} = 623.21\) kA at 0.28 \(\mu\)s.

Therefore, neon yield \(Y_{\text{sxr}}\) can be improved by reducing \(L_0\) from its value of 30 nH.

To compute the optimum \(L_0\) together with its corresponding optimum combination of \(z_0\), \(a\) and \(b\) for improving the neon yield \(Y_{\text{sxr}}\) from the optimized UNU/ICTP PFF, the values of \(V_0 = 14\) kV and \(C_0 = 30\) \(\mu\)F are kept constant throughout the present numerical experiments. We compute six sets of optimum configurations of \(z_0\), \(a\), \(b\) and \(L_0\) at six operating \(P_0 = 2.0, 2.5, 3.3, 4.0, 5.0\) and 6.0 Torr, respectively. Because, our aim is to find an optimum combination of \(z_0\), \(a\), \(b\) and \(L_0\) and also investigate the effect of operating pressure \(P_0\) on the neon yield \(Y_{\text{sxr}}\) for improving it.

In these numerical experiments, for each value of \(L_0\) the corresponding \(r_0\) is computed, so that the factor RESF \([\text{RESF} = \text{stray circuit resistance}/\text{surge impedance}; r_0/\sqrt{(L_0/C_0)}]\) remains unchanged at 0.2. Again, for each \(L_0\) the values of \(a\) and \(b\) are adjusted in such a manner that their ratio \((c = b/a)\) remains at a constant value of 3.368 (Ref. 16) and \(L_0\) was varied from 110 nH to 3 nH at each operating pressure \(P_0\).

The following procedure is applied to get the optimum combination of \(L_0\), \(z_0\), \(a\) and \(b\) at each operating pressure \(P_0\) for getting an improved value of neon yield \(Y_{\text{sxr}}\) (Ref. 16):

(i) The value of \(P_0\) is kept constant at a certain value for all values of \(L_0\) and also the value of \(z_0\) is fixed at a certain value for each \(L_0\).

(ii) Then \(a\) and correspondingly \(b\) are varied keeping \(c = 3.368\), until the maximum neon yield \(Y_{\text{sxr}}\) is computed for a certain value of \(z_0\).

(iii) Then \(a\) and correspondingly \(b\) are varied keeping \(c = 3.368\), until the maximum neon yield \(Y_{\text{sxr}}\) is computed for a certain value of \(z_0\).

(iv) Also \(a\) as well as \(b\) are varied with different values of \(z_0\) at each \(L_0\) to obtain the optimum combination for the maximum neon yield \(Y_{\text{sxr}}\).

(v) After that another value of \(z_0\) is chosen, the maximum neon yield \(Y_{\text{sxr}}\) is computed by varying \(a\) and \(b\) and so on, until we have the optimum combination of \(z_0\), \(a\) and \(b\) for the best improved neon yield \(Y_{\text{sxr}}\) at a fixed value of \(L_0\).

(vi) The above procedure is repeated with gradually reducing \(L_0\) until it reached 3 nH.

(vii) Then another value of \(P_0\) is taken and the procedure in (i)–(v) is followed carefully to compute the optimum combination of \(z_0\), \(a\) and \(b\) for the best improved neon yield \(Y_{\text{sxr}}\) at each value of \(L_0\) and so on.

Since the time taken by the plasma CS to reach the anode end needs to coincide with the rising time of \(I_{\text{peak}}\) for the maximum energy transfer to the crucial pinch region, \(z_0\) needs to be reduced with the reduction of \(L_0\) for time matching as \(I_{\text{peak}}\) comes earlier, as illustrated in Fig. 5. At the same time, because of reducing \(L_0\), the value of \(I_{\text{peak}}\) increases as a result \(a\) as well as \(b\) were necessarily increased.
Neon soft X-ray yield optimization in a low-energy DPF device

Fig. 6. Computed values of yield $Y_{\text{sxr}}$ and its corresponding optimum electrode geometry with respect to $L_0$ at 14 kV, 30 $\mu$F and 2.0 Torr with neon gas.

leading to longer pinch length ($z_{\text{max}}$) and hence a bigger pinch inductance [$L_p = (\mu/2\pi) \times \ln(b/r_p) \times z_{\text{max}}$] is found. Thus, the geometry of the machine moved from a longer and thinner (Mather-type) one to shorter and fatter (Filipov-type) one, as shown in Fig. 6. As $L_p$ increases with decreasing $L_0$, the dynamic pinch inductive load increases.

The values of $a$ as well as $b$ are varied with different values of $z_0$ at each $L_0$ to compute the optimum combination of them for getting the maximum neon yield $Y_{\text{sxr}}$, which corresponds closely to the largest $I_{\text{pinch}}$. The computed maximum possible values of neon yield $Y_{\text{sxr}}$ along with the corresponding efficiencies at $P_0 = 2.0$ Torr for each $L_0$ and the corresponding optimum combinations of $z_0$, $a$ and $b$ are presented in Table 1.

Table 1 shows that as $L_0$ is reduced, $I_{\text{peak}}$ increases and at each reduction of $L_0$ the corresponding $I_{\text{peak}}$ is larger than the previous value. This occurs continuously without showing any sign of limitation as a function of $L_0$. Whereas, $I_{\text{pinch}}$ also
M. A. Malek et al.

increases gradually with reduction of \( L_0 \) and finally it reaches a maximum value of 212.59 kA at \( L_0 = 10 \) nH, then it starts to decrease and also the ratio of \( I_{\text{pinch}}/I_{\text{peak}} \) drops progressively with further reduction of \( L_0 \). Thus, \( I_{\text{peak}} \) does not show any limitation of increment while \( I_{\text{pinch}} \) has a maximum value as \( L_0 \) is progressively reduced. This pinch current limitation effect is not a simple one.

The following three reasons make the combined effect that limits \( I_{\text{pinch}} \) current:

(i) If \( L_0 \) is reduced to zero then \( I_{\text{peak}} \) would not be infinity because at \( L_0 = 0 \) though the surge impedance \( Z_0 = \sqrt{L_0/C_0} \) is zero, the dynamics of plasma CS produces an impedance\(^{30,31} \) which then becomes the dominating load to limit the value of \( I_{\text{peak}} \).

(ii) The capacitor bank will discharge within a short time through the focus pinch as \( L_0 \) is reduced to a very small value and it becomes more and more immediately coupled to the pinch.

(iii) For the energy distributions and the requirement to adjust \( z_0 \), \( a \) as well as \( b \), the situation requires that as \( L_0 \) is decreased, the ratio of \( I_{\text{pinch}}/I_{\text{peak}} \) reduces.\(^{32} \)

Looking at Table 1, it is also observed that as \( L_0 \) is reduced gradually, there is a corresponding increase in \( a \) as well as \( b \), whereas \( z_0 \) decreased progressively.

In addition, for each reduction of \( L_0 \), the plasma pinch dimensions (pinch radius \( a_{\text{min}} \) and pinch length \( z_{\text{max}} \)) increase as a result the neon yield \( Y_{\text{sxr}} \) increases [refer Eq. (1)]. From this table, it can be noticed that the neon yield \( Y_{\text{sxr}} \) increases as \( L_0 \) is reduced with its corresponding optimum combination of \( z_0 \), \( a \) and \( b \). This happens until the neon yield \( Y_{\text{sxr}} \) reaches a maximum value of 48.83 J with the corresponding efficiency of 1.16% at \( L_0 = 15 \) nH and corresponding combination of \( z_0 = 2.8 \) cm, \( a = 2.2 \) cm and \( b = 7.477 \) cm, beyond which the neon yield \( Y_{\text{sxr}} \) does not increases with further reduction of \( L_0 \). Therefore, this is an optimum configuration of UNU/ICTP PFF machine operating at \( P_0 = 2.0 \) Torr. At this optimized configuration the computed value of neon yield \( Y_{\text{sxr}} \) (48.83 J) is about 10 times higher than that of the measured value (5 ± 1 J). The bold text in Table 1 indicates the optimized values of \( z_0 \), \( a \), \( b \) and \( L_0 \) along with the corresponding neon yield \( Y_{\text{sxr}} \) and efficiency. The variations of optimum neon yield \( Y_{\text{sxr}} \) and its corresponding optimum combination of \( z_0 \), \( a \) and \( b \) with \( L_0 \) are shown in Fig. 6. This figure shows that neon yield \( Y_{\text{sxr}} \) increases with reduction of \( L_0 \) and after a certain minimum value of \( L_0 \), neon yield \( Y_{\text{sxr}} \) starts to decrease. From the careful observation of this figure, it is seen that the optimum values of \( a \) and \( b \) gradually increase, whereas \( z_0 \) proportionally decreases with each reduction of \( L_0 \).

Since our motivation is to improve neon yield \( Y_{\text{sxr}} \) from UNU/ICTP PFF by computing the optimized combination of \( z_0 \), \( a \) and \( b \) for each \( L_0 \) (from 110 nH to 3 nH), we carry out a lot of numerical experiments at other five operating \( P_0 \) (i.e. 2.5, 3.3, 4.0, 5.0 and 6.0 Torr) following a similar procedure as discussed above. From the computed results, it is observed that the values of \( I_{\text{peak}} \), \( I_{\text{pinch}} \) and \( Y_{\text{sxr}} \) increase for each reduction of \( L_0 \) along with its corresponding optimum combination of \( z_0 \), \( a \) and \( b \) at each operating pressure \( P_0 \).
At each $P_0$, the increment of $I_{\text{peak}}$ has no limit with the reduction of $L_0$ while at a certain value of $L_0$, $I_{\text{pinch}}$ achieves a maximum value and then starts to reduce for further decrease of $L_0$ due to pinch current limitation effect. It is observed that in the optimization of $z_0$, $a$ and $b$ with $L_0$ of UNU/ICTP PFF operating at $P_0 = 2.0$, 2.5 and 3.3 Torr, the computed maximum neon yield $Y_{sxr}$ is found at $L_0 = 15 \text{ nH}$.

From Table 2, it is observed that the optimum combination of $z_0 = 2.10 \text{ cm}$, $a = 1.71 \text{ cm}$ and $b = 5.759 \text{ cm}$ is obtained at $L_0 = 10 \text{ nH}$ when it is operated at $P_0 = 4.0 \text{ Torr}$ and at this configuration the computed maximum neon yield $Y_{sxr}$ is found to be 57.16 J with a corresponding efficiency of 1.94%.

Here, the optimum $L_0$ is lower than our previously computed optimum value at a lower operating pressure. The bold text in Table 2 shows the optimum results. This computed value is about 11–12 times higher than the measured value ($5 \pm 1 \text{ J}$).

Similarly, at $P_0 = 5.0 \text{ Torr}$ and 6.0 Torr, the optimum combinations of $z_0$, $a$ and $b$ of UNU/ICTP PFF are obtained at $L_0 = 10 \text{ nH}$ with the maximum neon yield $Y_{sxr}$.

The summarized results of optimization of $L_0$, $z_0$, $a$ and $b$ of UNU/ICTP PFF at six operating pressures $P_0$ are presented in Table 3.

From Table 3, the effect of $P_0$ on optimization of $z_0$, $a$, $b$ and $L_0$ can be analyzed as follows:

- From this table, it is found that at each $P_0$ the optimum neon yield $Y_{sxr}$ is found to be almost constant at $v_a \sim 6.2 \text{ cm/\mu s}$ and the corresponding maximum pinch temperature $T_{\text{pinch}} (~2.4 \times 10^6 \text{ K})$ is also constant. This value of $T_{\text{pinch}}$ is very close to the temperature window of neon plasma for radiating maximum soft X-ray. So, these computed neon yield $Y_{sxr}$ are reasonably good.

- It is also observed from this table that at lower $P_0$ (say 2.0, 2.5 and 3.3 Torr), each optimum combination of $z_0$, $a$ and $b$ is found at $L_0 = 15 \text{ nH}$ for which the maximum neon yield $Y_{sxr}$ is obtained, but for higher $P_0$ (say 4.0, 5.0 and 6.0 Torr) the maximum yield is found at $L_0 = 10 \text{ nH}$. Technically, it is difficult and

### Table 2. The optimum combinations of $z_0$, $a$, and $b$ at an operating pressure of $P_0 = 4.0 \text{ Torr}$ with their corresponding neon yield $Y_{sxr}$ at fixed $c = b/a = 3.368$, $V_0 = 14 \text{ kV}$, $C_0 = 30 \mu F$, $\text{RESF} = 0.2$, $f_m = 0.05$, $f_c = 0.7$, $f_{mr} = 0.2$ and $f_{cr} = 0.8$.

</table>
expensive to have a capacitor bank with inductance less than 15 nH. Therefore, the optimization of $z_0$, $a$, $b$ and $L_0$ is good at lower $P_0$.

- This table shows that the minimum pinch column radius ($a_{\text{min}}$) is almost constant at $\sim 0.16$ cm and its maximum length ($z_{\text{max}}$) varies in the range of $\sim (3.5-2.4)$ cm at each optimum combination of $z_0$, $a$, $b$ and $L_0$ for each $P_0$. At the optimum combination of $z_0$, $a$, $b$ and $L_0$ for each $P_0$, the $z_{\text{max}}$ gets its maximum value than all other optimum combinations of them. It is clear from Eq. (1) that neon yield $Y_{\text{sxr}}$ is directly proportional to $z_{\text{max}}$. So, it is one of the important reasons for getting maximum neon yield $Y_{\text{sxr}}$ at the optimum combination of $z_0$, $a$, $b$ and $L_0$.

- In addition, it is noticed that the optimum values of both $a$ and $b$ decrease with increase of $P_0$.

A correlation among the optimum neon $Y_{\text{sxr}}$ yield and $L_0$ at six operating $P_0$ of our optimization is depicted by a three-dimensional plot which is illustrated in Fig. 7. Figure 7 shows that neon $Y_{\text{sxr}}$ yield rises proportionally with increasing $P_0$ from its lower value keeping fixed $L_0$ at 15 nH, whilst after a certain value of $P_0$, neon $Y_{\text{sxr}}$ yield starts to reduce remaining constant $L_0$ at 10 nH. The maximum value of neon $Y_{\text{sxr}}$ yield is found at higher $P_0$ but at low $L_0$. From the comparison of the computed neon $Y_{\text{sxr}}$ yield from Fig. 7 with the measured one (Ref. 2), from the comparison of the results (from Table 3), it is found that the variation trend of computed neon yield $Y_{\text{sxr}}$ with $P_0$ at different optimized configurations of $z_0$, $a$, $b$ and $L_0$ of UNU/ICTP PFF is similar with the measured neon yield $Y_{\text{sxr}}$ at different $P_0$ of the standard of UNU/ICTP PFF. The maximum measured neon yield $Y_{\text{sxr}}$ ($5 \pm 1$ J) has been found at the optimum $P_0 = 3.0$ Torr for the standard machine, while the maximum computed value of it (57.2 J) is obtained at an operating pressure $P_0 = 4.0$ Torr for our optimized configuration and then neon yield $Y_{\text{sxr}}$ drops on both sides of this $P_0$. This maximum computed value of neon yield $Y_{\text{sxr}}$ for optimized configuration is about 11–12 times higher than the measured value for the standard machine.
In addition, using the modified Lee model code, neon yield $Y_{sxr}$ of our optimized configuration is computed at each $P_0$ and $V_0 = 11.5$ kV keeping fixed the minimum pinch temperature ($T_{\text{pinch,min}}$) within the temperature window of neon gas (around $1.9 \times 10^6$ K) by merely adjusting $f_{mr}$ and the computed results are presented in Table 4. The measured neon yield $Y_{sxr}$ of NX2 machine at $P_0 = 1$–5 Torr and $V_0 = 11.5$ kV have been collected and placed in this table.

From Table 4, it is found that the speed factor (SF) at each optimum configuration of $z_0$, $a$, $b$ and $L_0$ is nearly constant ($\sim 102$). The constancy and similarity of SF to its standard value justify the computed results in Table 4. The maximum measured neon yield $Y_{sxr}$ (18 J) was found at 3 Torr and $z_0 = 5$ cm. In our optimization, each optimum value of $z_0$ is lower than that of the standard NX2. It is observed from Table 4 that the neon yield $Y_{sxr}$ with the corresponding efficiencies of our optimized machine are higher than those of NX2.

Based on the obtained results of these sets of numerical experiments with neon gas, it can be said that to improve the neon yield $Y_{sxr}$, $L_0$ should be reduced to a value around 15–20 nH, which is an achievable range incorporating low-inductance technology, below which the pinch current $I_{\text{pinch}}$, the yield $Y_{sxr}$ as well as the corresponding efficiency would not be improved significantly, if at all. Moreover, the neon yield $Y_{sxr}$ may be improved 11–12 times from the standard UNU/ICTP PFF value by a remarkable increase in $b$ and $a$ with reducing $z_0$ and $L_0$, keeping $c = b/a$ constant at 3.368 in the laboratory. In addition, significant reduction of $z_0$ and slightly increase in $b$ from the standard NX2, the neon yield $Y_{sxr}$ is also enhanced.

6. Conclusions

The Lee model code (RADPFV5.15de) is applied to characterize and optimize the UNU/ICTP PFF operated at 14 kV and 30 $\mu$F as a source of neon yield $Y_{sxr}$. The reduction effects of $L_0$ along with its corresponding optimum combination of $z_0$, $a$ and $b$ on the neon yield $Y_{sxr}$ at six operating pressures $P_0$ are investigated through a lot of numerical experiments. The limitation effect of $L_0$ on neon yield $Y_{sxr}$ is also observed from these numerical experiments. It is observed that with the optimization of $L_0$, $z_0$, $a$ and $b$, the optimum neon yield $Y_{sxr}$ increases with increasing $P_0$ up to 4.0 Torr and then it starts to decrease with further increasing $P_0$. The computed neon yield $Y_{sxr}$ from the optimized machine at different $P_0$ vary in the range of 48.83–57.16 J which is 10–11 times higher than the experimentally measured value ($5.4 \pm 1$ J) of the standard UNU/ICTP PFF. At $P_0 = 4.0$ Torr, the maximum neon yield $Y_{sxr}$ (57.2%) is obtained at $L_0 = 10$ nH. Though, at higher operating $P_0$, the optimum neon yield $Y_{sxr}$ shows higher value but $L_0$ gets to such low values that are difficult to achieve practically. Therefore, the best optimum combination of $L_0 = 15$, $z_0 = 3.0$ cm, $a = 1.85$ cm and $b = 6.231$ cm is computed at $P_0 = 3.3$ Torr and then the optimum neon yield $Y_{sxr}$ is found to be 54.6 J with the corresponding efficiency of 1.86%. Finally, our obtained optimized configuration through numerical experiments may be used to design a new device to have better soft X-ray yield than both the UNU/ICTP PFF and NX2.
